Kraus observed as early as 1900[2,3] that the conductance of non-aqueous salt solutions, when plotted against temperature, first increases, passes through a maximum and, thereafter, continues to decrease until the critical temperature of the solvent is reached. This phenomenon was ascribed by him to a continuous decrease of the dissociation constant for ion-pair formation with increasing temperature[4], which can only occur in solvents of a fairly high dielectric constant ε. (In these media the product εT, determining K, decreases as T increases.)

It is possible, however, to combine both phenomena and to give a more quantitative explanation of the conductance effect.

Combination of equation 1 with the fundamental electrochemical equations giving the relationship between ionic dimension (Stokes' law) and mobility, viscosity of the solvent and degree of ionization of the electrolyte, gives the following relation between the conductivity κ (in ohms^{-1} cm.$^{-1}$) of the solution and the absolute temperature :

$$\ln \kappa \approx -\frac{\dfrac{A_1}{2} + \dfrac{\Delta E}{R}}{T} + A_4 - \frac{A_3}{2} T \qquad (2)$$

in which ΔE denotes the activation energy of viscous flow, R the gas constant per mole and A_4 is another constant, independent of temperature.

As $\Delta E/R$ is positive, it follows from equation 2 that $\ln \kappa$ will reach a maximum value at the temperature :

$$T_m = \sqrt{\left\{\left(A_1 + \frac{2\Delta E}{R}\right)\Big/ A_3\right\}}$$

Thus it is clear that the effect observed by Kraus is a general phenomenon, valid for all electrolytes that are slightly ionized in the solutions considered.

By choosing a suitable solvent composition, the maximum in the conductivity can be brought into

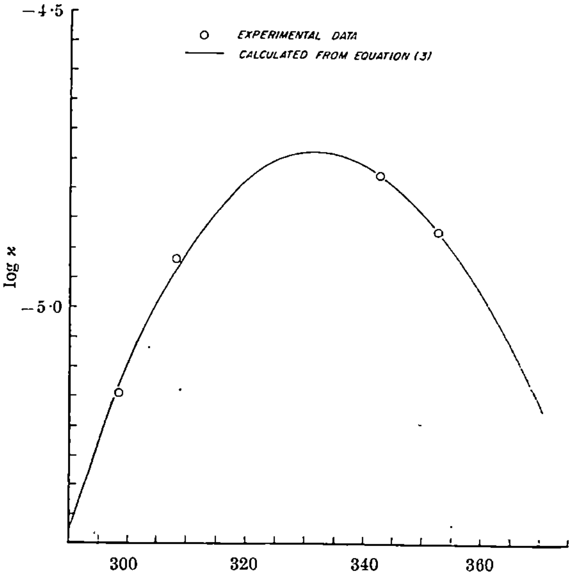

Fig. 1. Temperature dependence of the conductivity of 0·01 N acetic acid in water-dioxan (1 : 1 v/v)

a more accessible temperature region than Kraus observed. Examples are:

(1) 0·01 N acetic acid in water–dioxan (1 : 1 v/v), $T_m \approx 60°$ C.;

(2) 0·009 N perchloric acid in ethanol–benzene (21 : 34 v/v), $T_m \approx 60°$ C.

The first example is illustrated by Fig. 1. The conductivity curve drawn has been calculated from:

$$\log \varkappa = -\frac{11{,}760}{T} + 66{\cdot}14 - 0{\cdot}107\,T \qquad (3)$$

The coefficients in this equation have been determined from the experimental results.

Further details will be published elsewhere.

My thanks are due to Dr. E. A. M. F. Dahmen for his interest in this investigation.

Change of Inclination of a Satellite Orbit

In a recent article, Merson and King-Hele[1] state that the inclination of the orbit of satellite 1957β decreased by about 0·15° during its life and that this could not be accounted for by any effect of the Earth's ellipticity. The decrease appears to be a consequence of the cross-wind produced by the Earth's rotation.

If α is the inclination, λ the latitude, β the angular distance from apex, Ω the angular momentum, T the period and D the length of a sidereal day, then the track crosses the lines of latitude at an angle $\sin^{-1}(\sin\alpha\sin\beta\sec\lambda)$. The angle between the track and the apparent wind is $\tan^{-1}\left(\frac{T}{D}\sin\alpha\sin\beta\right)$ and this produces a couple about the line of apices the magnitude of which is a fraction $\frac{T}{D}\sin\alpha\sin^2\beta$ of that of the retarding couple. For a satellite rotating in the same direction as the Earth and impulsively retarded at perigee:

$$\frac{d\alpha}{dt} = \frac{T}{\Omega D}\sin\alpha\sin^2\beta\,\frac{d\Omega}{dt}$$

For an orbit of small eccentricity T is proportional to Ω^3 so that:

$$\frac{d\alpha}{dT} = \frac{\sin\alpha\sin^2\beta}{3D}$$

Table 1

T (min.)	Age (days)	β (degrees)	$\sin\alpha \sin^2\beta$	$\delta\alpha$ (degrees)	α (calc.)	α (obs. ± 0·02)
103·8	0	−31	0·24	−0·015	65·321°	65·331°
101	53·5	−51	0·55	−0·027	306	309
98	98	−71	0·81	−0·034	279	272
95	132·5	−86	0·90	−0·036	245	232
92	152·5	−96	0·90	−0·030	209	204
89·5	160	−99	0·89		179	192

It is seen that the values found for the variation of α can be fitted to Merson and King-Hele's curve within the observational error; the variation is therefore predictable and gives no information not otherwise attainable.

In view of this there seems no point in elaborating the analysis to take account of the spread of the resistance around perigee and the effects of the following wind and the variation with height of the angular velocity of the atmosphere.

Irregularities of Satellite Drag and Diurnal Variations in Density of the Air

A marked change in the slope of the period – time curves of *Sputnik* 2, *Sputnik* 3 and *Sputnik* 3 rocket has been reported, and from this it has been thought probable that the density of the air at a height of 220 km. increases considerably[1] somewhere between lat. 35° N. and 28° N.

An alternative explanation is that the sudden increase in drag is associated with the passage of the perigee from the night-side to the day-side of the Earth. In this case, the change is brought about chiefly by the precession of the orbital plane, instead of by the rotation of the perigee in the orbital plane. As the orbital plane rotates, the perigee is taken from the night-side to the day-side of the Earth, into air that has just been carried through the day-time side by the Earth's rotation; this being in the opposite sense to that of the orbital plane.

As the orbital plane precesses about ten times faster than the perigee rotates in the orbital plane, this explanation seems to account for the suddenness of the change more easily. An appreciable arc of the orbit near perigee could pass from the night-side to the day-side of the Earth in less than a day at the time of year when the terminator is at its smallest inclination (1·4°) to the orbital plane. At its greatest inclination (48°) to the orbital plane, the change-over would take about ten days.

For *Sputnik* 2, it is found that perigee passed into sunlight on December 23, 1957, the angle between orbit and terminator being nearly maximum. The observed change in slope of the period–time curve occurred over an interval of several days centred at about December 30. For *Sputnik* 3, rocket and satellite, the perigees passed into sunlight on July 13 and 14, 1958, the angle between orbit and terminator being nearly a minimum, whereas the observed changes in the slope of the period–time curves appear in the region of July 20 and 24 respectively. The correspondence is very close, and the consistent difference of about a week would be reduced if the calculated dates were based on a solar zenith distance of slightly less than 105°, which is the zenith distance of the horizon as seen from a height of 220 km. When the Sun's zenith distance increases beyond about 85°, the heat input would fall off rapidly due to the increasing length of path through the atmosphere. Assuming the cooling process to be of the same order of rapidity, so that 85° is the solar zenith distance at which the change occurs instead of 105°, the calculated dates become December 29, 1957, for *Sputnik* 2 and July 20 and 22, 1958, for *Sputnik* 3, rocket and satellite.

Other dates on which the perigees of the Russian Earth satellites passed or will pass into daylight (solar zenith distance less than 85°) are March 19, 1958, for *Sputnik* 2, October 24, 1958, for *Sputnik* 3 rocket, and October 30, 1958, January 30, 1959, for *Sputnik* 3 satellite.

The dates on which the perigees passed or will pass out of daylight (solar zenith distance greater than 85°) are February 4, 1958, for *Sputnik* 2, June 11, September 6 and December 12, 1958, for *Sputnik* 3 rocket and June 9, September 9 and December 14, 1958, for *Sputnik* 3 satellite. The existence of a sharp *fall* in air density at perigee on these dates depends on the rate of heating of the night air as it passes into sunlight. This may be so slow that the change in the slope of the period – time curve is not detectable against the fluctuations due to changes in the aspect of the rocket.

Clearly, more observations are needed before variations in density in the upper atmosphere and the processes causing them can be fully understood. The solar heating which appears to be responsible for the increase of density at 220 km. probably occurs at much lower heights, perhaps in the region of 100 km., and the expansion of the air at this level lifts the atmosphere above. The use of spherical satellites would eliminate the fluctuations in the period – time curve due to changes of aspect of the rocket, and allow variations in density to be studied with very much greater precision. It should then be possible to follow tidal variations of air density. These have not so far been picked out and are largely unknown at great heights.

Secondary Oscillations in an Equatorial Atlantic Deep-Sea Core

PRIMARY oscillations, corresponding to long-period changes in temperature in the upper layer of the sea, have been reported in long cores from Equatorial and North Atlantic, the Caribbean and Mediterranean Seas[1-3]. These changes, apparently the equivalent of glacial and interglacial periods, have been followed by: oxygen-18/oxygen-16 measurements on selected species of Foraminifera which deposit their tests in the upper layer of the sea; determining the proportions of planktonic Foraminifera characteristic of warm, temperate and cool waters; carbonate analyses and grain size determinations.

Cores from Atlantic abyssal plains are unsuitable for determining these changes because in these environments sediment is transported on the deep-sea floor from higher to lower levels. An undisturbed chronological sequence of sediments is frequently found in cores from the flat tops of isolated knolls, because they are outside the zone of turbidity currents.

Investigations have been made to determine whether undisturbed cores retain records of short-period temperature oscillations. A continuous series of ½-cm. sections have been taken from a core collected by the Swedish Deep-Sea Expedition (1947–48), from the top of a knoll in 1° 10′ N., 19° 50′ W. In this core the ratio of the sinistral to dextral tests of *Globigerinoides sacculifera* frequently changes by 20 per cent in ½ cm. It would therefore seem unlikely that the original sedimentary sequence has been appreciably disturbed by benthonic organisms.

Secondary carbonate oscillations, tentatively ascribed to short-period changes in temperature in the upper layer of the sea, were found superimposed on long-period changes[4]. It is unlikely that these oscillations are due to other causes because similar changes have now been found by determining in this core the annual rates of accumulation of: (1) calcium carbonate; (2) nitrogen; (3) fractions coarser than 500 and 250μ; (4) *Globorotalia menardii menardii*; and (5) *Globigerinoides sacculifera*. In collaboration with Dr. C. Emiliani and Mrs. T. Mayeda, oxygen-18 determinations have been made on the tests of *Globigerinoides sacculifera* isolated from 33 sections. There is a general parallelism between isotopic temperatures and rates of accumulation of calcium carbonate. It is, however, impossible to show by this technique whether the secondary carbonate oscillations are or are not reflexions of changes in temperature, because its accuracy is only about ± 1° C.

The age of the mid-point of each section, as well as its age range, was determined from the weights of titanium and iron in unit-area columns through each section. There is a variety of evidence which suggests that the rates of accumulation of these elements have not varied during the time interval represented by the core, and that there has been no post-depositional movement.

Some of the results, for the period 14,500 B.C.–4500 B.C., are shown in Fig. 1. There is at many points a sympathetic relation between the various methods. The rate of accumulation of *Globorotalia menardii menardii* was $\sim 0{\cdot}005$ μgm./cm.^{2}/yr. during the maximum phases of the last glaciation. The

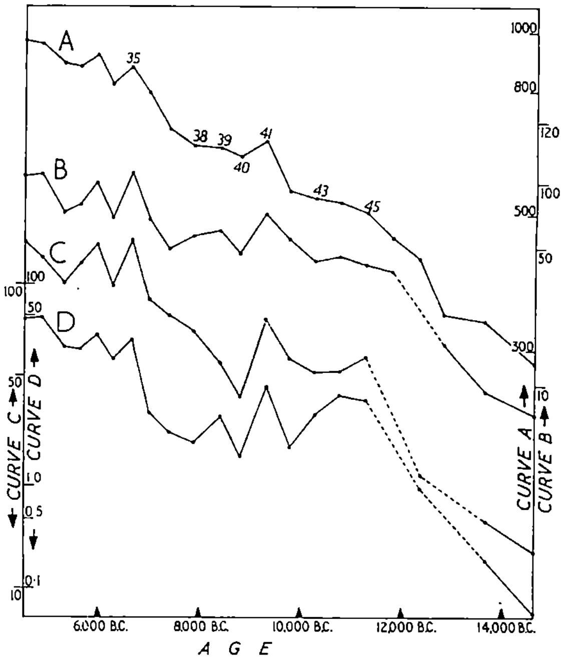

Fig. 1. Rates of accumulation (μgm./cm.^{2}/yr. on a log scale) of: (*A*) calcium carbonate; (*B*) fraction coarser than 500μ; (*C*) *Globorotalia menardii menardii* plus *Globigerinoides sacculifera*, and (*D*) *Globorotalia menardii mendardii*. Section Nos. are given on curve *A*

maximum rate, ~ 159 μgm./cm.²/yr. was attained in about A.D. 1200. Confirmation is therefore given to Schott's hypothesis[5] that in the equatorial Atlantic this species was rare during the maximum phase of the last glaciation.

The reliability of all the methods of determining past changes in temperature is subject to various conditions—for example, methods (3), (4) and (5) are affected by changes in the degree of fragmentation. Methods (4) and (5) are invalidated if the investigated species replaces, or is replaced by, another species characteristic of warm water. The sharp rise in the rate of accumulation of *Globorotalia menardii menardii* between section Nos. 43 and 45 (Fig. 1*D*) is apparently related to this effect, because there is no notable increase in the combined rates of accumulation of *Globorotalia menardii menardii* and *Globigerinoides sacculifera* (Fig. 1*C*).

Thirty of the minor changes in the annual rates of accumulation of calcium carbonate may be correlated with secondary climatic changes in Europe and North America. For example, the oscillation at 9200 B.C. (section No. 41) is correlated with the well-established climatic amelioration in pollen zone II (the Alleröd oscillation). The radiocarbon age of zone II*b* at Wallensen, Germany, is 9200 B.C.[6], and its equivalent in eastern Wisconsin—the Two Creeks interval—has been dated by Arnold and Libby as 9450 B.C.[7]. The temporary return to cold in zone III is represented by section Nos. 40–39 (8750 B.C.–8350 B.C.). In Denmark the ages of the lower and upper limits of the Younger Dryas are, respectively, 8900 B.C. and 8350 B.C.[8], while its equivalent in eastern Wisconsin—the Valders glacial maximum—is dated 8700 B.C.[9].

The period of increasing temperature, 7850 B.C. (section No. 38)–6600 B.C. (section No. 35), apparently corresponds in Europe to the retreat of ice from the central Swedish moraines, and the Yoldia marine transgression in the Baltic. In the southern North Sea peat beds, containing a Maglemose harpoon-head[10], were apparently flooded after 6450 B.C.[11]. It is of interest to report that a small ridged flake of grey flint (British Museum, 1957, 663) was collected south of the Dogger Bank (53° 50·5′ N., 1° 40·0′ E.) in July 1957 by Lieut.-Commander C. J. de C. Scott while in command of H.M.S. *Shackleton*. Dr. K. P. Oakley considers that this could be Upper Palæolithic or Mesolithic.

In North America there is a period of increasing warmth marked by the rapid retreat of the ice from the Valders moraines in Wisconsin to those near Cochrane, Canada[12].

In view of the apparent correlation between secondary changes in the upper layer of the equatorial Atlantic and climatic changes in Europe and North America it is desirable, on climatological grounds, to discover whether similar oscillations occurred in other oceans. Cores from the Indian Ocean, collected by the John Murray Expedition (1933–34) and housed in the British Museum (Natural History), although unsuitable for detailed work of this nature, clearly indicate past temperature changes in the upper layer of this ocean. It is therefore hoped that when the preliminary programme for work in the Indian Ocean suggested by the Special Committee on Oceanic Research[13] is reviewed, consideration will be given to the desirability of collecting undisturbed cores from suitable sedimentary environments, and the necessity of training research students in the various techniques.

Polarographic Study of Acid-Base Reactions of the Tropylium Ion

A POLAROGRAPHIC study of the tropylium ion $(C_7H_7^+)$ in unbuffered media[1] did not permit any quantitative interpretation of the acid-base phenomena at the surface of the mercury dropping electrode. We therefore followed the reduction of the tropylium ion in well-buffered media. At concentrations lower than about 0·00015 *M* one irreversible reduction wave was observed. The height of this wave decreased with increasing *p*H in the form of a dissociation curve (Fig. 2) with $pK' = 5{\cdot}64$ at $t_1 = 3{\cdot}3$ sec. The kinetic current at higher *p*H values is limited by the rate of formation of the reducible tropylium cation from electro-inactive

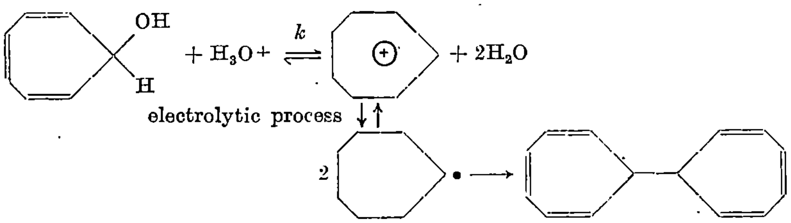

Fig. 1

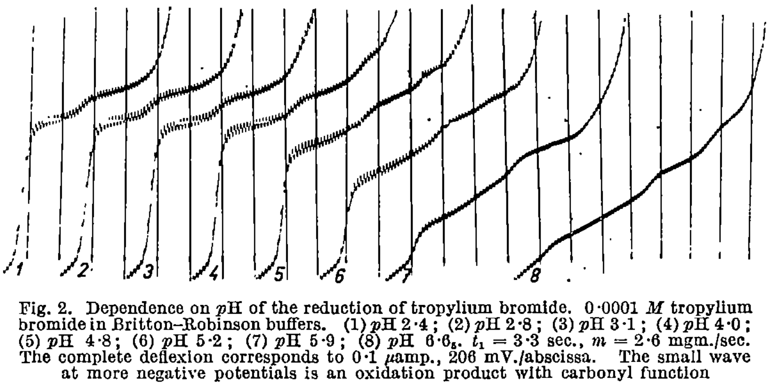

Fig. 2. Dependence on *p*H of the reduction of tropylium bromide. 0·0001 *M* tropylium bromide in Britton–Robinson buffers. (1) *p*H 2·4; (2) *p*H 2·8; (3) *p*H 3·1; (4) *p*H 4·0; (5) *p*H 4·8; (6) *p*H 5·2; (7) *p*H 5·9; (8) *p*H $6{\cdot}6_5$. $t_1 = 3{\cdot}3$ sec., $m = 2{\cdot}6$ mgm./sec. The complete deflexion corresponds to 0·1 μamp., 206 mV./abscissa. The small wave at more negative potentials is an oxidation product with carbonyl function

tropyl alcohol, which is present in the solution and is brought by diffusion to the surface of the mercury electrode.

The reduction proceeds by a one-electron step to a radical, with subsequent formation of ditropyl, as in the reduction by zinc[2]. The formation of the dimer was proved[3] by the shift of the half-wave potential with increasing tropylium bromide concentration. The half-wave potential at pH lower than 4·6 is independent on the pH ; at higher pH it shifts to more negative values according to the equation $E_{1/2} = -0{\cdot}25 - 0{\cdot}040\ p\mathrm{H}$ (standard calomel electrode). The slope of the curves is 0·040. All the phenomena observed are consistent with the mechanism indicated in Fig. 1.

Neither the character of the dissociation curves nor the pK' values are affected by the buffer components, by the pyridinium ions or by the ionic strength. Using the equation derived by Koutecký[4] and the value $pK = 4{\cdot}6$, determined by titration, the rate constant for the formation of tropylium ion was calculated as $k = 2 \times 10^6$ l. mole^{-1} sec.$^{-1}$.

At concentrations of the tropylium ion higher than about 0·001 M, three types of adsorption processes were observed. Using the value for the lowest adsorption wave, the surface-area (S), covered by one reduced seven-membered ring at the surface of the mercury drop, was calculated by Brdička's equation[5] as 29 A.^{2}. Using covalent radii and bond distances[6], S was calculated as 22 A.^{2}. Adsorption processes were studied using i–t curves, $\bar{i}$–t curves, single-sweep polarography, oscillographic polarography, etc. Detailed results will be published elsewhere.

We are indebted to Mr. C. R. Ganellin (Queen Mary College, University of London) for the sample of tropylium bromide.

Origin of Time-dependent Organization in a Micelle Series

The question of physical equilibrium in homogeneous solution may be stated as follows : At what stage of molecular complexity can a solute exist in non-equilibrium for times which are very long in relation to the scale of molecular processes ? The complex linear micelles formed by the interaction of naphthol and a quaternary soap are able to exist[1] and contrary to expectation[2], the simple micelles formed by the same soap alone[3]. The purpose of this communication is to show at what point in a homologous series such persistent non-equilibrium arises.

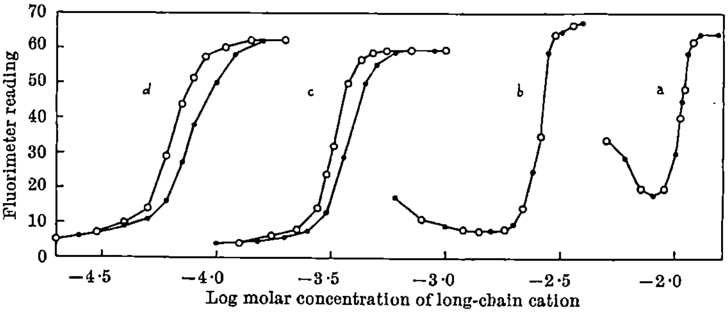

Fig. 1. Use of fluorescent dye in discriminating between different states of a cationic soap solution. Fluorescence of μM dichlorofluorescein as a function of concentration of four cationic soaps at 25° C. *a*, C12 trimethyl ammonium bromide in 4 mM sulphate ; *b*, C14 in 0·24 mM sulphate ; *c*, C16 in 0·05 mM sulphate and *d*, C18 in 0·024 mM sulphate. ○, Stock soap added to diluted salt ; ●, stock salt added to diluted soap

The compounds chosen were the C12, 14, 16 and 18 paraffin-chain trimethyl ammonium bromides, in aqueous solution around the critical micelle concentration, with a low concentration of sodium sulphate to develop the non-commutative property. This meant that the chemical potential could depend on the order in which the components were added (from relatively strong stock solution) as well as on the final composition. Sulphate was used rather than halide to minimize supersaturation[4]. Non-equilibrium was detected by fluorescence quenching, using dichlorofluorescein as the marker. The method depends on the sensitiveness of the dye/micelle adsorption complex to chemical potential ; full details are being submitted elsewhere together with a theory based on accepted principles.

In numerous experiments at 25° C. it was found that solutions of the C12 and C14 soaps were always completely defined by their composition, so that all the experimental points fell on a single curve (Fig. 1). This was not true for the others ; the curve split into two parts, the upper part referring to solutions in which sulphate had been added first, and the lower to those in which soap had been added first, as predicted by theory. The possibility of superimposable organization in homogeneous solution seems, therefore, to arise at a very early stage in molecular complexity, in micelles of a paraffin-chain salt with 16 or possibly 15 carbon atoms. Because of water-structure effects with quaternary compounds[4,5], not apparent with anionic ones, the critical chain-length is probably a little greater for the latter.

FORTHCOMING EVENTS

(*Meetings marked with an asterisk * are open to the public*)

Monday, December 1

Royal Society (at Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Anniversary Meeting.

British Society for the History of Science, Philosophy of Science Group (in the Joint Staff Common Room, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. R. S. Peters: "A Defence of Aristotelianism in Psychology".

Society of Engineers (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Mr. T. J. Hawker: "Some Industrial Applications of Magnetic Power".

University of London (in the Physiology Lecture Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. Z. M. Bacq (University of Liège): "Substances which Protect Against Ionizing Radiations"* . (Further lecture on December 3.)

Royal Institute of Chemistry, London Section (joint meeting with the London Section of the Society of Chemical Industry, at the Society of Chemical Industry, 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Dr. J. L. Edgar: "The Production of Petrochemicals in Holland".

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 8.30 p.m.—Mr. A. R. Akester: "Saharan Survey".

Tuesday, December 2

University College (in the Physiology Theatre, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. W. S. Feldberg: "Some Physiological Aspects of General Anæsthesia".*

Institution of Mechanical Engineers, Education Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "The Planning of Mechanical Engineering Teaching Laboratories".

Society of Chemical Industry, Corrosion Group (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Discussion of Three Research Papers published in the *Journal of Applied Chemistry*.

Wednesday, December 3

University of London (at the Postgraduate Medical School of London, Ducane Road, London, W.12), at 2 p.m.—Dr. R. I. S. Bayliss: "Laboratory Investigations in Endocrinology".*

Society for Analytical Chemistry (joint meeting with the Association of Public Analysts, at the Wellcome Building, Euston Road, London, N.W.1), at 3 p.m.—Symposium on "Food Analysis"

Royal Statistical Society (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.15 p.m.—Discussion on the Report of the Committee on the Supply of and Demand for Statisticians.

Institute of Fuel (at the Institution of Civil Engineers, Great George Street, London, S.W.1), at 5.30 p.m.—Mr. G. W. Lee: "The Work of the British Coke Research Association".*

Institute of Petroleum (at 61 New Cavendish Street, London, W.1), at 5.30 p.m.—Mr. J. F. Hutton: "Flow Properties of Distillates at Low Temperatures: a Review"; Mr. H. Strawson: "The Pumpability of Aviation Turbine Fuels at Low Temperatures".

University of London (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. O. E. Lowenstein, F.R.S.; "Sensory Function and Qualitative Information".* (Further lectures on December 4 and 5.)

Society of Chemical Industry, Plastics and Polymer Group (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Mr. D. A. Boyle, Mr. W. Simpson and Dr. J. D. Waldron: "The Characterization of Short Chain Branches in Hydrocarbon Polymers".

Radar and Electronics Association (at the Royal Society of Arts, John Adam Street, Adelphi, London, W.C.2), at 7 p.m.—Dr. R. L. F. Boyd: "Exploration of the Upper Atmosphere by Rockets and Satellites".*

Thursday, December 4

Royal Society (at Burlington House, Piccadilly, London, W.1), at 10.30 a.m.—Discussion on "The Effect of Environment Upon Molecular Energy Levels" opened by Dr. H. W. Thompson, F.R.S.

Linnean Society of London (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Exhibition Meeting.

Institute of Refrigeration (at the Institute of Marine Engineers, The Memorial Building, 76 Mark Lane, London, E.C.3), at 5.30 p.m.—Mr. G. L. H. Bird, Dr. J. C. Fidler, Mr. W. B. Gosney and Colonel H. Randal Steward: Review of the Moscow Meetings of the International Institute of Refrigeration.

Institution of Electrical Engineers (in conjunction with the British Nuclear Energy Conference, at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. D. W. Fry: "A Review of Work towards Nuclear Energy from Controlled Thermonuclear Reaction".

Physical Society, Acoustics Group (in the Physics Department, Imperial College, London, S.W.7), at 5.30 p.m.—Dr. P. T. Haskell: "Insect Acoustics".

Royal Anthropological Institute of Great Britain and Ireland (at 21 Bedford Square, London, W.C.1), at 5.30 p.m.—Prof. C. von Fürer-Haimendorf: "Monastery and Village among the Sherpas of Nepal".

Royal Institution, Library Circle (at 21 Albemarle Street, London, W.1), at 5.30 p.m.—Dr. A. S. C. Lawrence: "Sir James Dewar and the Royal Institution".

Society of Chemical Industry, Microbiology Group (at 14 Belgrave Square, London, S.W.1), at 6.15 p.m.—Meeting on "Preparation of Vaccines". Dr. P. W. Muggleton and Miss J. P. Farmer: "Preparation and Standardization of Freeze-Dried B.C.G. Vaccine". Dr. J. A. Dudgeon: "Preparation of Viral Vaccines".

Polarographic Society (at "The Duke of York", 8 Dering Street, London, W.1), at 7 p.m.—Informal Discussion Meeting on "Some Polarographic Problems Encountered in the Food Industry" introduced by Dr. T. L. Parkinson.

Royal Institute of Chemistry, London Section (joint meeting with the Battersea College of Technology Chemical Society, at the Battersea College of Technology, Battersea Park Road, London, S.W.11), at 7 p.m.—Prof. A. R. Ubbelohde, F.R.S.: "Melting Mechanisms of Ionic Crystals".

Thursday, December 4—Friday, December 5

British Institute of Radiology, incorporated with the Rontgen Society (at Church House, Westminster, London, S.W.1)—Annual Congress and Exhibition.

Friday, December 5

Institution of British Agricultural Engineers (at 6 Buckingham Gate, London, S.W.1), at 2.15 p.m.—Paper: "How Far are British Tillage and Harvesting Machines Meeting Overseas Conditions?" (Informal Meeting).

University of London (at Senate House, London, W.C.1), at 5.30 p.m.—Dr. W. H. Glanville: "Motorways".*

Society of Chemical Industry, Pesticides Group (together with the Agriculture Group and the Fine Chemicals Group, at 14 Belgrave Square, London, S.W.1), at 5.45 p.m.—Joint Meeting on "Gibberellic Acid". Dr. P. W. Brian: "The Effects of Gibberellic Acid on Plant Growth"; Dr. B. E. Cross: "The Chemistry of Gibberellic Acid".

Institution of Mechanical Engineers (in conjunction with the British Nuclear Energy Conference, at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Mr. K. G. Mantle, Mr. N. Marshall and Dr. P. J. Palmer: "An Experimental Investigation into the Stress Distribution in a Band Reinforced Pressure Vessel".

Society of Dyers and Colourists, London Section (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 6 p.m.—Dr. J. L. Stoves: "Dyeing of Furs".

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Dr. Richard van der Riet Woolley, F.R.S.: "Stellar Motions and the Structure of the Universe".

Saturday, December 6

Association of Agriculture and the British Agricultural History Society (at the Institute of Education, University of London, Malet Street, London, W.C.1), at 11 a.m.—Agricultural History Conference.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Senior Lecturer in Radiochemistry in the Department of Chemistry and Biology, College of Technology, Liverpool—The Director of Education, City of Liverpool Education Committee, 14 Sir Thomas Street, Liverpool 1 (December 5).

Assistant Librarian (with a good honours degree) in the Science Libraries—The Registrar, The University, Liverpool (December 6).

Assistant Physicist (with a good honours degree in physics) in the Physics Department of the Sheffield National Centre for Radiotherapy—The Secretary, Sheffield Regional Hospital Board, "Broom Cross", Tree Root Walk, Sheffield 10 (December 6).

Lecturer (with a good honours degree in mining engineering and postgraduate research and/or industrial experience) in Mining Engineering—The Registrar, King's College, University of Durham, Newcastle-upon-Tyne (December 6).

Chair of Metallurgy—The Registrar, The University, Manchester (December 8).

Scientific Officer, Grade 3 (with an honours degree in metallurgy, chemical engineering or chemistry, or other academic qualifications and research achievements considered the equivalent) at the Weapons Research Establishment of the Department of Supply, near Adelaide, South Australia, for research into high-temperature materials with special reference to rocket motors and high-velocity rocket missiles—The Senior Representative (AV/9/12), Department of Supply, Australia House, Strand, London, W.C.2 (December 8).

Lecturer or Assistant in Organic Chemistry—The Registrar, The University, Leeds (December 15).

Post-Doctoral Research Fellow in the Department of Fuel Technology and Chemical Engineering, to direct and carry out research on the laws of smoke formation and elimination with all types of fuel—The Registrar, The University, Sheffield (December 15).

Micro-Biologist (with a good honours degree in botany or agricultural botany) at the Welsh Plant Breeding Station, for work associated with the breeding of new strains of clover—The Registrar, University College of Wales, Aberystwyth (December 20).

Senior Lecturer or Lecturer (Grade I or II) in Geology initially in the Geography Department, University College, Ibadan, Nigeria, to develop teaching of geology in the Faculty of Science and to assist with geology teaching for the Faculty of Agriculture—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (December 22).

Lecturer in the Department of Zoology, and an Assistant in the Department of Zoology—The Secretary, The University, Edinburgh (December 27).

Fellow (with previous research experience in either radio astronomy or astronomy) in Radio Astronomy in the Division of Radio Physics, Commonwealth Scientific and Industrial Research Organization, Sydney, to take part in an active research programme in some aspect of radio astronomy—Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting Appointment No. 780/194 (December 31).

Senior Lecturer or Lecturer in Agricultural Botany, a Lecturer in Inorganic Chemistry, a Lecturer in Mathematics, and Lecturers (2) in Botany at the University of Khartoum—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (December 31).

Lecturer (electrical engineer or physicist) in Electrical Engineering—The Registrar, University College of South Wales and Monmouthshire, Cathays Park, Cardiff (January 13).

Chair of Agricultural Chemistry—The Registrar, University College of Wales, Aberystwyth (January 17).

Senior Fellow or Fellow (with qualifications, interests and experience in some physico-chemical aspect or aspects of biochemistry) in the Department of Physical Biochemistry, John Curtin School of Medical Research, Australian National University, Canberra—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, January 19).

Assistant, Grade B (graduate, preferably with teaching and/or industrial experience) in Physics, to teach up to B.Sc. and H.N.C. standard—The Clerk to the Governors, Mid-Essex Technical College and School of Art, Market Road, Chelmsford.

Assistant Lecturer, Grade B (with a degree or equivalent qualification, and preferably industrial and/or research experience) in Chemistry—The Principal, Medway College of Technology, Horsted, Maidstone Road, Chatham, Kent.

Assistant Lecturer, Grade B (with an honours degree in geography and teaching experience), in Geography, preferably with Social Studies as subsidiary subjects—The Principal, Coventry Technical College, Coventry.

Biochemist in the Endocrinology Laboratory—The House Governor, Royal Marsden Hospital, Fulham Road, London, S.W.3.

Bradford City Council Research Scholar (honours graduate in chemistry or biochemistry) in the Department of Chemical Technology, to work on some aspect of protein chemistry related to the keratins—The Registrar, Institute of Technology, Bradford 7.

Experimentalist (physical or inorganic chemist, preferably with a degree) in the Electromagnetic Separation Team investigating the chemistry of most elements including plutonium, using many physical and engineering techniques—The Group Recruitment Officer (1249/34), U.K.A.E.A., Atomic Energy Research Establishment, Harwell, Berks.

Lecturer or Senior Lecturer in Metallurgy in the Department of Mechanical Engineering—The Registrar, Royal Technical College, Salford 5.

Lecturers and Senior Lecturers (with an honours degree in engineering or equivalent qualification) in the Department of Mechanical Engineering—The Registrar, Royal Technical College, Salford 5.

Librarian (woman, with a degree in biology or zoology)—The Secretary, Bureau of Animal Population, The University, Botanic Garden, Oxford.

Research Physicist (preferably with experience in the use of ultra-high vacuum systems or in the chemical physics of surfaces) in the Department of Physics, for work involving electrical measurements applied to the study of surface contamination processes on semiconductors—The Professor of Physics, University of Reading, Physics Research Laboratories, Upper Redland Road, Reading, Berks.

Scientific Officer (Chemist) (with a good honours degree in chemistry, postgraduate experience in food analysis, and preferably a knowledge of fumigant and insecticide analysis) in the Department of Marketing and Exports, Federation of Nigeria, to undertake research into problems associated with the storage of oil seeds and other food crops with particular reference to insect infestation with the object of evolving methods for reducing losses—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.153/14/05.

Scientific Officer (with a good honours degree in botany or agriculture, and preferably some postgraduate experience in agronomic methods and a knowledge of field experimentation statistics) with the West African Maize Research Unit, Nigeria, to take charge of agronomic work with maize and to conduct trials in maize husbandry—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.197/375/02.

Senior Agronomist (with a university degree in agriculture or a degree in natural science with a postgraduate diploma in agriculture and experience in field experimental studies, preferably with perennial tree crops) at the West African Cocoa Research Institute, Ghana, to take charge of the Agronomy Section and co-operate with senior specialist officers in the field of experimental work of the Institute—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.197/200/010.

Senior Histological Technician—Prof. H. P. Gilding, Department of Physiology, Medical School, Birmingham 15.

REPORTS and other PUBLICATIONS

(not included in the monthly Books Supplement)

Great Britain and Ireland

Engineering Materials and Design, Vol. 1, No. 1 (October, 1958). Pp. 58+48A. Published monthly. Annual subscription 35*s.*; 5.25 dollars. Single copies 2*s.* 6*d.* (London: Heywood and Co., Ltd., 1958.) [239

Hill Farming Research Organisation. First Report, 1954–58. Pp. 88. (Edinburgh: Hill Farming Research Organisation, 1958.) [239

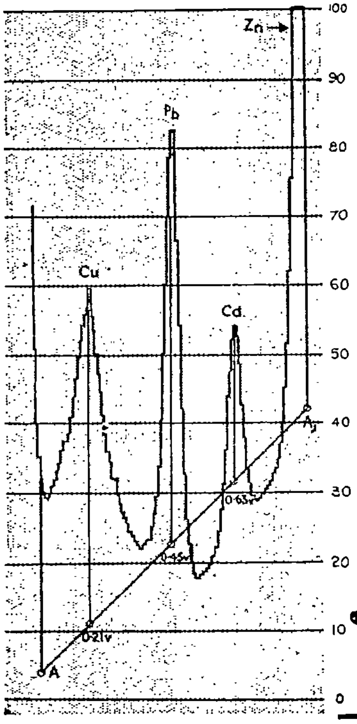
* COPPER · LEAD · CADMIUM....with ZINC

How long would it take to analyse



by CONVENTIONAL METHODS, a solution having the following metals present —

COPPER	3 p.p.m.	CADMIUM	2 p.p.m.
LEAD	7 p.p.m.	ZINC	200,000 p.p.m. ?

These Square Wave Polarograms recorded by the

MERVYN-HARWELL
SQUARE WAVE POLAROGRAPH Mk. III

are reproduced here to show the identification of these metals, in these proportions, in solution. Note the high ratio of Zn to Cd., without interference. The peaks are identified by the automatic potential markers AA1, which enable half-wave potentials accurately to be established. Permanently recorded on a 10" wide chart.

**This was an actual problem presented to Mervyn Instruments by a leading chemical manufacturing organisation.*

Speediest, most Accurate, the Fundamental Development in Analysis—and therefore the most Economic. Convenient in Design, Sensitive in Application.

Send for our full technical leaflets, quoting "Nature" to

HUMAN RELATIONS IN INDUSTRY

THE final report of the Joint Committee on Human Relations in Industry* covers the three ıars from the issue of the Committee's first report March 1954 until, on the termination of the Con-tional Aid Scheme on March 31, 1957, the Joint ımmittee, like that on Individual Efficiency in .dustry, was disbanded. Eventually, in November '57, the Council for Scientific and Industrial esearch set up a permanent Human Sciences Com-ittee to advise on future support by the Department Scientific and Industrial Research for research in ese sciences, especially that relating to the design equipment, training and human relations in dustry. The work carried out by both Joint Com-ittees is briefly reviewed in reports which are here blished under one cover ; but the main interest of th reports lies in their discussion of policy and rvey of the general position of research in this ld.

The period of office of the two Committees has tnessed a real development of research in the ld of human relations in industry and a big growth industrial interest in such research. Both oppor-nities and needs are now more clearly understood, d although the work of both Committees was minated, and probably excessively so, by the funds ıde available under the Conditional Aid Programme d derived from United States economic aid, which t to research being concentrated on the study of oblems arising out of practical situations, the Com-ttee on Human Relations in Industry believes that luable lessons can be learnt from its experience. w lines of study, for example, were opened up and w ideas introduced into academic thinking. The mation of new research groups was prompted and ilitated, and these groups and many recently alified workers have been attracted to the study human problems in industry.

Nevertheless, the Committee points out that such ditions can lead to distorted effort, and those es of research which add to underlying knowledge t are only indirectly relevant to immediate prac-al purposes are liable to be neglected. Studies of s character provide the foundation essential to rt-term investigations of practical problems, and Committee takes the view that future arrange-nts for financing social research from public funds uld provide for work of a basic, long-term char-er. It does not, indeed, appear from these reports t this undue reliance on Conditional Aid Funds , in fact, to the promotion of projects of dubious ue, as was suggested at the time (cf. *Nature*, 174, 1954) ; but it is scarcely to the credit of Britain that in accepting the generous offer of the United States this lack of balance should have been allowed to develop through failure to supply the further funds which already in 1954 were recognized as needed. The newly established Human Sciences Committee intends to encourage both basic and applied research for the promotion of the growth of psychology and sociology, and to make further contributions to the solution of the practical problems of industry and society ; but Government support could equally well have been used five years ago to check the obvious tendency of Conditional Aid Funds to divert effort from such fundamental research.

The Committee on Human Relations in Industry recognizes that fundamental and applied research in this field are closely related. Some of the best projects it has sponsored have combined an attack on practical problems with penetration of underlying theoretical issues. It suggests that it is characteristic of social science that the best results come from those who are able to operate at both the practical and theoretical levels ; but nevertheless, the Committee is convinced that opportunities must be available for research workers of high calibre to pursue fundamental studies.

Nor is this the only problem of balance. It is equally important to correct the piecemeal character of much social research in industry, and ensure that the right targets are selected. The Committee sought to meet the criticism from industry that the problems studied by academic social scientists are trivial, or of past, rather than present, interest, and that the priorities are wrong, by going to industry for suggestions ; some research arising from suggestions originating from industry was included in its programme. Its experience, however, led to the conclusion that academic research groups readily welcome suggestions from industry concerning the problems that merit study ; any reticence on their part is usually related to difficulties in arriving at a research method and plan that will meet scientific requirements and in finding competent research workers. Further, to develop a bare suggestion for research into a realistic research project requires much further discussion and detailed formulation, and, in consequence, a considerable amount of effort from the industrial organization responsible for the suggestion.

To secure the contribution of both the research group and the industrial organization is thus not a simple proposition ; but the Committee is convinced that industrial needs will only be properly reflected in the research programmes of academic research groups if this joint approach is widely adopted. Real progress depends on individual research groups finding ways and means of associating industry more closely with their work, not only in its execution and

Department of Scientific and Industrial Research. Final Report he Joint Committee on Human Relations in Industry 1954–57 Report of the Joint Committee on Individual Efficiency in stry 1953–57. Pp. vi+44. (London: H.M. Stationery Office, .) 3s. net.

in the application of its results but also in the choice of the problems to be investigated.

Nor is such a balanced effort solely a matter of collective judgment on the part of those sponsoring the research. Administrative arrangements can also be an important factor, in that as these at present stand there is no point at which both the funds available and the whole range of projects to be considered are known. The Human Sciences Committee will not be effective unless public financial support for social research programmes has much more continuity than in the past. A settled policy of support is needed and *ad hoc* administrative arrangements should be terminated.

Before considering the Committee's comments on the ways in which financial assistance should be given, there is a further factor to be considered which bears on this question of continuity. The main obstacle to the healthy growth of social research in industry remains the shortage of trained people. The Committee admits that only a few project leaders capable of planning and directing research have emerged as a result of the work done during the past three years. This crucial deficiency is attributed to the lack of reasonable career prospects; for this reason, research organizations are faced with a steady drain to industry of their best people just when they promise to be most useful—as senior scientists competent to take immediate charge of research projects under the general supervision of the director of research.

Since many of the social research groups are built around one senior person, whose transfer to industry means the disintegration of the group, the Committee concludes that a main object of future public support should be to create a number of stable research groups of viable size, characterized by a higher ratio of senior to junior staff, so as to reduce vulnerability as well as provide adequate supervision, and by a sufficient size to provide young research workers with an intellectually stimulating environment in which to learn the craft of research. Moreover, such a step should contribute towards establishing the independence of social research workers, a matter on which the Committee also lays great stress. It considers that Britain is fortunate in that social research workers have been able to maintain the impartiality and independence of their scientific role, but its continuance depends on ability to gain and retain confidence. It is essential here that social research workers should recognize that the choice between different social objectives is a matter for those directly concerned in the industry, and not for them in their scientific capacity.

The Committee distinguishes three types of research groups which require financial assistance. For those seeking to enter the field but possessing neither the experience nor the proved competence to focus their research interests immediately and to formulate an appropriate research method, assistance should be limited to a period of two or three years. The work of the more mature groups, with well-developed industrial contacts, is probably best su
ported on the basis of individual projects over a
agreed period. But neither group can develop t
measure of stability in personnel and the long-ter
scientific strategy needed for fundamental research
its finance is wholly *ad hoc*. Besides these tw
groups, the Committee visualizes grants by t
Department of Scientific and Industrial Research
the Medical Research Council to enable the unive
sities or independent research institutes to crea
stable research units for the study of subjects
joint interest.

Apart, however, from indicating that the unive
sities or independent research institutes wou
be expected normally to provide the necessa
foundation of uncommitted, long-term support, a
emphasizing the importance of social research
industry being recognized as an established universi
interest to be supported by normal university fund
the Committee does not seem to consider the implic
tions of such a system or how co-ordination a
balance are in practice to be secured. The Committ
does not attempt to re-open the question whether
not a Social Science Research Council should now
established, and it could scarcely have been expect
to ask whether the Department of Scientific a
Industrial Research or the Medical Research Coun
is the most appropriate body either to co-ordina
social science research or to distribute public fun
for such research. These, however, are the critic
questions, and they require further discussio
especially in the light of evidence that the Depa
ment of Scientific and Industrial Research and ev
the Lord President's office as at present constitut
are unable to function effectively in that way, a
also in relation to the wide issues on the control
expenditure on research raised by the recent repo
of the Select Committee on Estimates.

In the light of the evidence submitted to th
Committee, it seems essential that the method
distribution of research grants and the way in whi
expenditure is to be controlled and co-ordinat
should be carefully considered before any ne
administrative arrangements are made for resear
grants, especially through existing bodies. Moreov
in view of what the Committee remarks about t
importance of associating more of the larger indu
trial firms with research and the development
research teams in this field, it might be well
associate industry with the development of any su
administrative arrangements. To do so could w
lead to suggestions for improved arrangements, a
the independent foundations may also have somethi
to contribute here, apart from what they are alrea
doing to encourage growing points in actual researc
Indeed, the Committee on Human Relations
Industry stresses the importance of seeking c
operation from the many institutions the intere
of which could be brought to bear on the developme
of social research in industry, and refers specifica
to the technical colleges, the industrial resear
associations and national bodies concerned wi
industry.

The Human Sciences Committee is stated to be king up proposals for research on a relatively large ale from certain well-established research groups hich between them cover the whole field from perimental psychology to sociology; but it seems ore than a little doubtful whether a body within e Department of Scientific and Industrial Research n have either the authority and status—or the sources—to ensure development of a co-ordinated ogramme of research, quite apart from the question hether this is the appropriate point from which ch an attempt should be made. This is not to ggest that the Department can make no contriution in its own right: on the utilization of results d questions of communication it has a growing lume of experience, including some current studies, hich should be of direct assistance, and research sociations should also be able to help in the selection problems, not simply those bearing on productivity t equally with regard to industry in its broad cial context and in relation to future developments. evertheless, even the Council for Scientific and dustrial Research seems likely to lack the standing at is required to put social research in industry on e basis that is now required.

The Joint Committee on Individual Efficiency in dustry has little to add about policy; but that ttle is in line with what is said by the Committee n Human Relations in Industry. It does not, deed, regret the initial emphasis on short-term search in its programme, as at the present stage of evelopment the success of such projects and the use f their results in industry are likely to provide fresh deas for basic research and open up new facilities for research workers in industry. It is, however, equally convinced of the need for balanced activity, and sees the need in the future to encourage the parallel growth of fundamental and applied research and the application of results. Moreover, it recognizes even more explicitly that action is required which goes beyond the particular responsibilities of the Medical Research Council and the Council for Scientific and Industrial Research, and it recommends in particular that certain problems of training and of the supply of trained scientific man-power—including the need to teach future engineers something of the difference between the characteristics of the human being and the machine—should be referred to the Lord President for comprehensive examination.

That particular proposal is open to Sir Hugh Beaver's recent criticisms; but it does indicate the need for a much wider examination of the situation and at a high level, at least by the Advisory Council on Scientific Policy, the observations of which on the report should be made without delay. This is even more urgent and fundamental than the survey of research needs which the Department of Scientific and Industrial Research is already undertaking. The Joint Committees have analysed the situation and needs with admirable lucidity and exemplary restraint, and their reports supply all that is needed to enable those concerned to ensure that research into the social and human problems of industry should be adequately supported and competently pursued, to press for the further examination at the appropriate level of the administrative problems of financial support and control, and the co-ordination of such research as well as the interpretation and communication of its results.

SCIENTIFIC APPARATUS IN THE ROYAL INSTITUTION*

By Sir LAWRENCE BRAGG, F.R.S.

THE stores of the Royal Institution contain many interesting examples of apparatus which has een used for research or lecture demonstrations, or hich has been given or bequeathed to the Instituon. The most valuable and historic pieces are on ermanent display in the ambulatory around the cture theatre. An overhaul of the collections has cently been undertaken, and in the course of this ork many treasures have been rediscovered and teresting facts about their history have come to ght. It is not easy to select from such a wealth of aterial. The examples to be mentioned may seem o have little connexion with each other. But, taken gether, they form a connected story, because they ll date from at least eighty years ago and they utline the state of knowledge at that time, the henomena in which the physicists were mainly terested, the kind of apparatus they used for emonstration, and the instrument makers' art of he period. The examples will be chosen from the ain branches of physics: mechanics, sound, light, lectrostatics, and electromagnetism.

The first example is a mechanical model for illustrating the combination and interference of waves (Fig. 1), and is a very elegant piece of instrumentation. It came to the Royal Institution in the De la Rue collection. Warren De la Rue was elected a member of the Royal Institution in 1851, and made a number of gifts during his lifetime. After his death, his widow presented his collection. The instrument shows five wave-forms simultaneously; the motions of the white beads on its upper part are always the sum of the

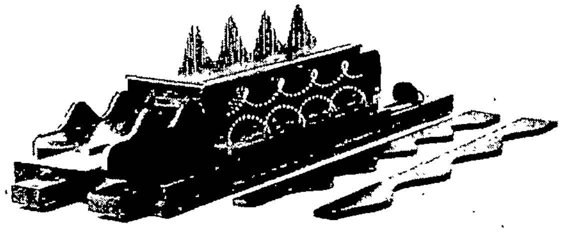

Fig. 1

---

* Substance of a Friday Evening Discourse at the Royal Institution elivered on October 24.

two wave motions set on either side. The positions of the beads are determined by vertical and horizontal wave guides, and in an ingenious way the component waves can be given any phase and amplitude and various wave-lengths. It shows the combination of waves of different wave-lengths, interference of waves of the same wave-length, and plane, circular or elliptical polarization. It is said to have been designed by Wheatstone.

The next exhibit is one of the original Edison phonographs, shown by W. H. Preece before the Society of Telegraph Engineers on February 27, 1878. He said: "I may tell you that this instrument is only the second which Mr. Edison, the wonderful genius on the other side of the Atlantic, has ever made. It was brought over from America by my friend Mr. Puskas. . . . Some three weeks or a month ago I had the honour of lecturing before the Royal Institution and the phonograph then being a greater novelty than it is now, I had been promised by Mr. Edison an instrument for exhibition, but knowing that inventors cannot always fulfil their promises as to time . . ." (he took the precaution of having one made according to Edison's description). So although this early model arrived too late to be shown at the Royal Institution, it appears that it eventually found a home here; our specimen is identical in every way with that figured in Preece's paper. Tinfoil is pressed on to the surface of the cylinder with a grease adhesive. If one shouts "Mary had a little lamb" into the mouthpiece of the sound box while turning the handle, this classical poem is distinctly repeated when the needle on the sound box covers the same track again.

William Spottiswoode, who worked in the publishing firm of Eyre and Spottiswoode, became a member of the Royal Institution in 1864. He was a great amateur scientist, who equipped his own laboratory on a lavish scale. His collection of optical and electrical apparatus was presented by W. Hugh Spottiswoode in 1899, on the occasion of the centenary of the Institution. Spottiswoode gave a discourse in 1873 on "The Old and New Laboratories at the Royal Institution", and this, together with a description of his collection of apparatus, was reprinted as a pamphlet. It is a mine of information. One interesting sidelight is the following story which Spottiswoode told: "It is said that Mr. Fuller, the feebleness of whose constitution denied him at all other times and places the rest necessary for health, could always find repose and even quiet slumber amid the murmuring lectures of the Royal Institution, and that in gratitude for the peaceful hours thus snatched from an otherwise restless life . . ." he left a legacy to the Royal Institution for establishing the Fullerian professorship, which I now have the honour of holding. I hope some members of my audience to-night will be similarly moved. Spottiswoode's apparatus is distinguished for its costliness and rarity, as if he were determined to have the best and largest of everything. In particular, his Nicol prisms and tourmaline plates exhibited here are outstanding.

In 1879 W. E. Ayrton gave a discourse on "The Mirror of Japan and its Magic Quality". These mirrors are Chinese in origin, and called "mirrors that let the light pass through them". The back has a pattern in heavy relief. The front is brightly polished and appears to be quite uniform. If, however, the light from a bright point source is reflected on to a screen by the mirror, the pattern on the back is faithfully repeated in the patch of ligh The magic mirrors were known to antiquity (Ayrto says that they were described by Aulus Gellius i A.D. 100), though the origin of the magic propert was a mystery. So late as 1832 Sir David Brewst believed it was due to trickery, a slight etching scratching of the front surface having been made t correspond to the pattern on the back. The explan tion of the effect was first put forward by Govi in 186 as due to slight changes of curvature of the fac Ayrton, who had lived in Japan and had an oppo tunity of studying the manufacture of the mirror solved the mystery. The mirror is made slightl convex by scoring it in all directions with an iro rod before polishing, and the places where it is thic are less convex than those where it is thin, becau there is less yield to the strain created by the scorin process.

Electrostatic machines, and the electrostatic di charge in evacuated tubes, aroused the deepe interest. The Royal Institution has a long series electrostatic machines, from those of Nairne an Winter to a very large Wimshurst machine made b Wimshurst himself. The Spottiswoode collectio includes a large hammer-break induction coil whic gives a spark 17 in. long, and some hundreds discharge tubes which are beautiful examples glass-blowing. In these days of neon signs th phenomena of the discharge do not seem so strange t us as they did to former generations, but the excit tion of these tubes by the Spottiswoode coil is still very spectacular display.

An interesting 'gadget' from the United Stat depends upon the electrostatic discharge; it is a early form of gas lighter, presented to the Roy Institution in 1865. The advertisement (Fig. shows how it works. The turning of the ebonit knob and its sudden removal induces a charge o the cup, which discharges across the sparking point just above the jet and so lights the gas.

The next three examples show stages in th development of the dynamo. The Clarke machin (Fig. 3*a*) has coils on a yoke which rotates opposit the poles of a composite horseshoe permanent magne In the next stage, shown in Fig. 3*b*, Siemens designe an armature of a more modern form, and shape pole pieces, with a great improvement of the mag netic circuit, though permanent magnets were sti employed. It was then realized that an electr magnet would provide a more powerful field-magne

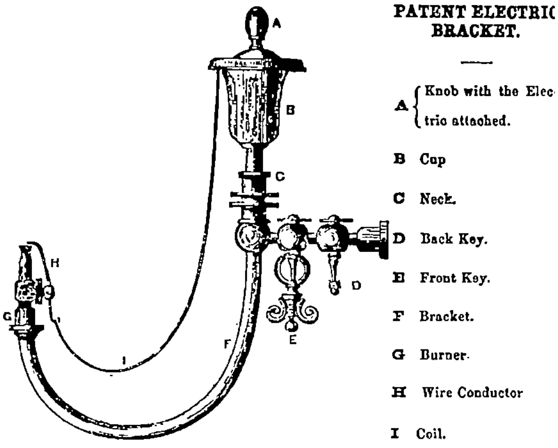

Fig. 2

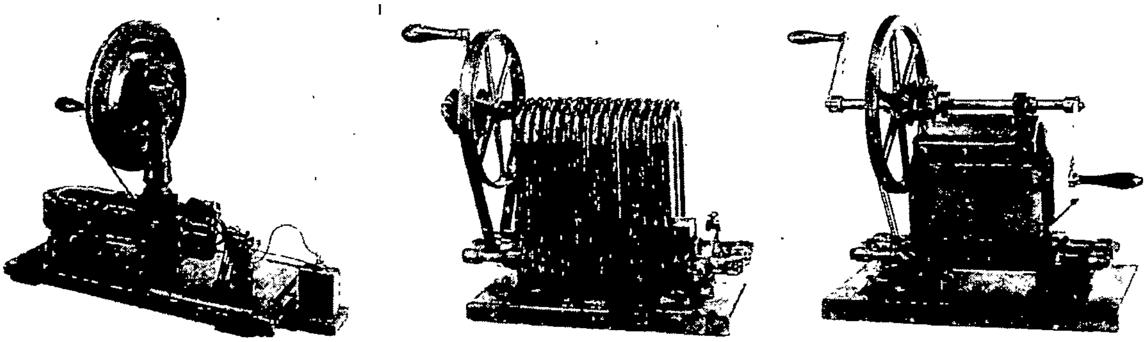

(a) (b) (c)

Fig. 3

so a small dynamo with permanent magnets was mounted above the main dynamo and excited the field. In Ladd's machine, shown in Fig. 3c, the idea was taken one stage further ; the armature has two windings, one to excite the field and one to provide the current. Finally, of course, it was realized that part of the main current from the armature could be diverted to exciting the field.

We appear to have no record of how my last exhibit reached the Royal Institution. It is a very early example of the use of microfilm, which we are accustomed to think of as a quite recent development. These samples date back to the siege of Paris in 1870–71. Messages could be got out of Paris by balloon, and attempts were made to get them back by carrier pigeon, but the pigeons were poorly trained and harassed by hawks and falcons sent up by the Prussians, so few got through. In its extremity, the Government called in the help of M. Dagron, who devised a way of photographing the messages greatly reduced in size and stripping the pellicle of film from the plate. Each pellicle had 3,000 letters on it, and a pigeon could carry twenty pellicles in a quill attached to its tail, so it was possible to repeat the messages almost indefinitely until reply came from Paris that they had reached their destination. So successfully did the system work that the public were allowed to use it at 50 centimes a word—a very interesting example of necessity being the mother of invention.

When one surveys the apparatus in the storerooms of the Royal Institution and thinks of the many great occasions in the past when they were shown at the discourses, one cannot but realize that this place, of which we are the trustees and guardians, is a national treasure house of a unique kind.

EFFECTS OF ATOMIC RADIATION

In December 1955 the General Assembly of the United Nations set up a scientific committee for assembling, studying, and finally summarizing all available evidence on levels of ionizing radiation and radioactivity and their effects on man and his environment. The committee members were drawn from fifteen States : Argentina, Australia, Belgium, Brazil, Canada, Czechoslovakia, Egypt (United Arab Republic), France, India, Japan, Mexico, Sweden, U.S.S.R., United Kingdom, and United States. A summary report was drafted during the fourth session of the committee in February 1958 and approved at its fifth session in June. It is based on 213 reports from member States and specialized organizations, such as the World Health Organization. Much use has obviously been made of the two extensive reports published in 1956 by the United States and the United Kingdom[1].

The report of the United Nations Scientific Committee consists of two parts*. The first, shorter, one contains summarizing chapters on physical data, fundamental radiobiology, somatic and genetic effects of radiations, and conclusions drawn from the available evidence. The second part presents the data and considerations which form the material for the first. It consists of a number of 'annexes', some with additional appendixes, all with extensive literature references and numerous tables and graphs, but differing in the amount of space allotted to discussion and speculation. Undoubtedly the most valuable feature of the report is the assemblage of world-wide tabulated data on all aspects of radiobiology : including physical aspects such as the amount of cosmic radiation, of fall-out, and of radium content of the water in many regions of the Earth, and biological aspects such as the estimated doses for doubling mutation-rates in various organisms, or the amount of strontium-90 and cæsium-137 adsorbed into the human body in different countries and under different nutritional regimes.

A considerable amount of data which appeared after the publication of the American and British reports had to be assimilated. The quantitative estimates of fall-out had to take account of the two facts that (a) some fission products of nuclear explosions do not reach the stratosphere and are brought down by rainfall and sedimentation from the troposphere, and (b) fall-out from the stratosphere varies with latitude, regions between 30 and 50° N. receiving a considerably higher deposition than the world-wide average. The estimates of damage from ingested radioisotopes are affected by data on the strontium–calcium balance in different soils and foodstuffs and by the recognition of cæsium-137 as an important isotope which, unlike strontium-90, is distributed fairly evenly through the body, including the reproductive organs. Vegetable food, which reaches the human body without processing by animals, contains considerably larger amounts of strontium than animal food. A given amount of fall-out is therefore expected to result in higher concentrations of strontium-90 in the bones of rice-eating than of milk-consuming peoples. Diagnostic X-rays are still regarded as the major source of man-made radiation to the human body. The committee states that in medically highly advanced countries the average gonad dose from this source may equal that received from natural sources. The British Medical Research Council, which in its 1956 report estimated the lower limit of the gonad dose from diagnostic X-rays in the United Kingdom as 22 per cent of the background dose, has now revised this opinion[2]. In its detailed critical comment of the United Nations report, the British Medical Research Council accepts the statement quoted above, but points out that the world average must be much smaller. Certain types of examination, especially by fluoroscopy, give very high doses to the bone marrow. Less radiation is contributed by radiotherapy and very much less by occupational exposures.

---

* Report of the United Nations Scientific Committee on the Effects of Atomic Radiation. (General Assembly—Official Records : Thirteenth Session, Supplement No. 17 (A/3838).) Pp. iii+228. (New York : United Nations ; London : H.M. Stationery Office, 1958.) 2.50 dollars ; 18s. ; 10.50 Swiss francs.

In spite of these additions and alterations, the conclusions drawn from the data are essentially the same as those arrived at by the two national reports. After defining the 'genetically significant dose' as the average gonad dose to the individual weighted by the expected number of children, the Committee accepts "that radiation-induced mutations are, in general, harmful and increase in direct proportion to the genetically significant exposure, even at very low dose levels; and that a dose of between 10 and 100 rads (the rad is the unit of absorbed radiation: it is very close to 1 r.) per generation would probably be required to double the natural mutation rate in human populations". On the basis of calculations which the British Medical Research Council accepts only with certain reservations, the Committee estimates that about 4 per cent of all births are affected with hereditary disorders, and that a permanent doubling of the mutation-rate would increase this number to between 5 and 8 per cent. Estimation of the somatic damage is made difficult by ignorance of the precise dose-relationship between radiation and leukæmia, cancer, and other somatic effects, including ageing. Calculations have therefore been carried out separately for two alternative assumptions: the existence of a threshold below which the individual is not harmed by radiation, and a linear dose-effect curve like that found for mutations. These assumptions give different quantitative results, but in either case "it must be recognized that the exposure of human populations to increasing levels of ionizing radiations may cause considerable and widespread somatic damage". In regard to the possible shortening of the average life-span by radiation, the report is somewhat more reserved than the American one and restricts itself to the statement that such a shortening does occur in experimental animals, and that "it is possible that the same may be true for man". The Committee quotes recent British data indicating a correlation between, on one hand, leukæmia and other cancers in childhood and, on the other, irradiation of the fœtus, but points out that alternative interpretations cannot be excluded.

The practical recommendations are essentially the same as those in the two national reports. The introduction of individual radiation certificates is considered impracticable at present, but it is recommended that radiologists and dentists keep records of the quantities and qualities of radiation used not only in therapeutic but also in diagnostic procedure The Committee concludes that the cessation of nuclear weapon tests would "act to the benefit of human health", but considers a more definite proposal in this sense outside its terms of reference. Two minority proposals, one by the U.S.S.R., approved by Czechoslovakia and Egypt (United Arab Republic) the other by India, approved by Brazil, France, Japan and the United States, are less reserved in stressing the biological dangers of nuclear weapon tests and the desirability of the cessation of such tests.

So many workers are at present engaged in radio-biological studies that a report of this kind can never be completely up to date. Among those recent results which could not be included, two may be singled out because of their potential significance for estimates of radiation hazards. One is the finding by Griffen that males of a Bent-Tail strain of mice which had been given 700 r. of X-radiation produced a fair number of semi-sterile sons during their post-sterile period, presumably from irradiated spermatogonia. In one case, the semi-sterility was shown to be due to a translocation; for the remaining 25, cytologica tests have not yet been carried out, nor is it clear whether the semi-sterile condition was transmitted to half the sons, as would be expected if it were in every case due to a translocation. In Griffen's opinion these data invalidate the current belief that the production of translocations in spermatogonia can be neglected in calculations of genetical radiation damage; but since this belief is founded on clear data, both in *Drosophila* and the mouse (including new unpublished results by W. L. Russell), it would seem better to reserve judgment until a full analysis of this surprising observation is available. The second important result which appeared too late for inclusion in the report is the observation by W. L Russell and E. M. Kelly[4] that low-intensity gamma radiation (90 r. per week) produced fewer mutations in mouse spermatogonia than the same dose given in one intense exposure of X-rays.

Since this finding is likely to be used as an argument in the discussion of genetical radiation hazards, three points should be emphasized. First, even with low-intensity radiation, the per locus mutation-rate is still several times as high as that obtained by intense irradiation of *Drosophila* spermatogonia (Russell, personal communication). Secondly, the low-intensity test was carried out mainly because the dose-effect curve for high intensities had shown an unexpected depression at high doses, suggesting the disturbing possibility that the mutation-rate at very low doses or intensities might be *higher* than expected on a linear dose-effect relationship; this possibility could be ruled out by the low-intensity data. Thirdly, Russell cautions that, because of the nature of the material, it is at present difficult to predict what the dose curve will be like at still lower intensities of radiation. Thus, it is certainly not safe to conclude that the data support the concept of a threshold dose for genetic effects.

The three major reports on radiation hazards clearly are addressed to different sections of the reading public: the American report to the 'man in the street', the British to the general reader who is willing to spend time and effort on a thorough study of the whole question, the United Nations report to the expert. It is therefore doubtful whether the long and often highly speculative discussions of specialized biological phenomena (such as the biochemical activities of mitochondria and microsomes; the effects of radiation on kappa particles in *Paramecium* and on prophage in lysogenic bacteria; the possible existence of mutator genes in human populations; and many others) are necessary or, indeed, helpful to an appreciation of the presented facts. The expert in a particular field will know the original literature. Others (for example, a physicist reading the sections about bacterial genetics) will scarcely be able to take in this wealth of information and speculation, let alone use it for the intended purpose, namely, as basis for a critical evaluation of radiation hazards. Limitation of the space devoted to discussion would also have avoided much tedious repetition and overlapping between chapters. These, however, are minor defects which probably will correct themselves through the reader skipping whatever does not interest him by being either too familiar or too unfamiliar. They do not detract from the high value of this impressive presentation of carefully collected and critically evaluated data and the considered judgments and recommendations based on them.

IODINE-131 IN HUMAN THYROIDS FOLLOWING THE WINDSCALE REACTOR ACCIDENT

By G. MAYCOCK and J. VENNART

Radiological Protection Service, Belmont, Sutton, Surrey

DURING the latter half of October 1957, following the Windscale reactor accident, we observed that the gamma-ray activity of certain members of the staff of the Radiological Protection Service, at Belmont, Surrey, was higher than expected from previous estimates of their body content of the naturally occurring isotope of potassium, potassium-40 and the fission product cæsium-137. The source of the greater part of this increased activity was identified as iodine-131, which had not occurred previously in the gamma-ray spectrum of these individuals, and there was also evidence of a slight increase in the cæsium-137 content. However, since iodine is concentrated in the thyroid gland, whereas cæsium is distributed throughout the body, it was evident that, so far as radiation damage to the individual might be concerned, only the increased amount of iodine-131 would be important. We decided, therefore, to make some measurements of the iodine-131 in human thyroids. In view of the account of the Windscale reactor accident[1] and the recent paper by Stewart and Crooks[2] reporting the subsequent contamination by nuclear debris of many parts of England, we are reporting our measurements as a matter of interest, since few organizations will possess the equipment and the low-background laboratory which is essential for the measurement of the low levels of thyroid activity reported here.

The measurements were made in a low-background laboratory using a sodium iodide (thallium) crystal, 2 in. × 1·75 in. in diameter, optically coupled to a photomultiplier tube, the output of which was fed via amplifiers to a 100-channel pulse-height analyser. For the measurement of an individual, this crystal was arranged over the thyroid with the curved surface touching the skin. The equipment was calibrated with a known amount of iodine-131 in two polyethylene bottles having dimensions very close to that of the lobes of an average thyroid. The bottles were strapped, 6 cm. apart, on to the neck of a model of the human body containing distilled water so that the centres of the model lobes were 3 cm. below the proximal crystal surface. This particular dimension was used, since measurements by one of us (J. V.) on more than a hundred persons submitted for diagnosis of thyroid function using iodine-131 had shown that the mean effective depth of the thyroid below the anterior skin surface was approximately 3 cm. The space between the model lobes and the crystal was packed with polyethylene to give an approximation to the actual case of a human neck. Although a larger distance between the crystal and the neck would have minimized errors due to variations in depth of thyroid below the surface of the skin, the method used gave reasonable accuracy and it had the merit, with regard to the low levels expected, of giving maximum sensitivity.

The iodine-131 in the thyroid of an individual was then assessed by comparing the counting-rate within the 0·36-MeV. photo peak of his gamma-ray spectrum with the corresponding counting-rate in the spectrum of the model. An appropriate correction, which was very small, was made for the contribution from potassium-40 and cæsium-137 within the individual's body. Each individual was measured for a period of 15 min.; the standard deviation due to counting-background amounted to 0·04 mμc. iodine-131. An idea of the reliability of these measurements may be obtained by comparing our measurements on one individual, person *K* in Table 1, who was a visitor from Leeds, with that made by Burch and Spiers[3] at Leeds. They found that this individual had 8·2 mμc. of iodine-131 in his thyroid on October 31 and 8·8 mμc. on November 2. These values are in excellent agreement with our own measurement, which was 8·5 mμc. on November 1.

Eighteen persons were measured, the majority of whom were resident either in, or on the fringe of, the Greater London area. The exceptions were persons *B* and *L*, who were resident in mid-Surrey but working in Belmont, and person *K*, who was a visitor from Leeds. Apart from *F* and *G* (two children aged 12 and 10½ years, respectively) the group comprised both male and female adults.

It was not convenient to make more than one measurement in the case of most of these individuals, but where series of measurements were possible they are listed in Table 1.

Table 1. Iodine-131 Content of Thyroid (in mμc.)

Subject	Date of measurement Oct. 1957 31	November 1957 1	4	5	8	15	22	Jan. 1958 2
A	2·6							
B	0·6							
C	1·8			1·5	1·0	0·7		
D	2·0					0·8		
E	2·1					0·2		
F	1·8							
G	1·3							
H		6·3		5·1	3·8	2·6	1·8	0·09
I		2·4			1·5			0·16
J		0·9						
K		8·5						
L		1·0						
M		1·2						
N		1·6	1·0					
O		1·4				0·3		
P			1·2					
Q				1·5	1·4	1·0		
R				0·6				

The results for the one person, *H*, on whom we were able to make a series of reliable measurements showed an elimination-rate from the thyroid which was slower than the radioactive decay-rate of iodine-131. This clearly indicates that the uptake of iodine-131 into the gland was continuing throughout the period of measurement. Since the atmospheric contamination of iodine-131 at the time of measurement was negligible[2], the only route of entry into human thyroids would be by ingestion, such as would result from the daily intake of milk obtained from cows grazing contaminated pastures. The fact that person *H*, who showed the highest value of iodine-131 in the thyroid for the London group, had by far the highest milk intake (at least two pints daily) also supports the view that the main source of iodine-131 was in milk. This is in agreement with the views expressed in the report of the accident[1]. Furthermore, we were able to detect iodine-131 in London milk during the period indicated in Table 1; but the activities were too low to state the amount with confidence.

All the persons listed in Table 1, apart from *K*, would have been drinking milk from a large London dairy during working hours, and all except *B* and *L* from one or other of the large London dairies while at home. The milk supply for the dairies comes from a wide area of the country around London.

In order to calculate the dose of radiation received by the thyroid, it is first necessary to know how the thyroid-level of iodine-131 varies with time after the event. Since the main route of entry to the human thyroid was via milk, then as the cloud with its iodine-131 from Windscale passed over Britain on October 11, we may expect that the first day on which milk contained this isotope was October 12. This is in agreement with the findings at Windscale reported by the committee of inquiry[1]. In the early days following the accident there might have been a period during which the activity in milk increased, since some delay would occur while the iodine-131 on the grass passes through the cow. When the level of iodine-131 in milk is in equilibrium with that on herbage, the activity in milk will decrease at a rate determined by radioactive decay and by other processes, for example, leaching by rain and decay of the vegetation. With regard to an estimation of the radiation-dose to the thyroid of a human drinking this milk, it is also necessary to consider losses of iodine-131 from the thyroid due to biological elimination and to radioactive decay. It is obvious, therefore, that the pattern of thyroid uptake and excretion may be very complex, especially during the early days after the accident. Our results relate to a period which begins several days after the accident, when we might expect the iodine-131 in milk had reached equilibrium with that on the grass. These results will therefore give no information about the pattern of the initial build-up in the thyroid. However, since our intention is to make an estimate only of the dose in the thyroid, the following simplification of the problem is permissible.

If we assume that the activity in milk decreases exponentially with time, and with the same decay constant, λ day^{-1}, as that for iodine-131 in the thyroid, then the amount of iodine-131 in the thyroid, *q* mμc., at any time, *t* days, after the initial ingestion, is given by the equation:

$$\frac{dq}{dt} = B \exp(-\lambda t) - \lambda q \qquad (1)$$

where *B* is the initial daily intake in mμc./day. Hence,

$$q \text{ (in m}\mu\text{c.)} = Bt. \exp(-\lambda t) \qquad (2)$$

The above assumption will be valid, and this equation will describe the pattern of uptake, and excretion, of iodine-131 from the thyroid if, for example, decrease of activity in milk and in the thyroid is principally by radioactive decay. Since the rate of biological elimination of iodine-131 from normal human thyroids is small[4], the effective decay constant in the thyroid will be only slightly greater than the radioactive decay constant of iodine-131, which is 0·087 day^{-1}. It is, perhaps, not surprising, therefore, that the results for person *H*, on whom the greatest number of measurements were made, can be fitted very closely (see Fig. 1) to equation 2 when $\lambda = 0{\cdot}1$ day^{-1}, $B = 2{\cdot}3$ mμc./day and *t*, in days, is measured from zero time, October 12.

By integrating the expression $Bt(\exp - \lambda t)$ over infinite time, it can be shown that the total thyroid dose of iodine-131 amounted to 230 mμc. days. Using values given in the Recommendations of the International Commission on Radiological Protection[4] for the effective energy per disintegration, 0·22 MeV., and the weight of the thyroid, 20 gm., it follows that the total mean radiation dose to the thyroid of person *H* due to the accident amounts to 0·13 rad.

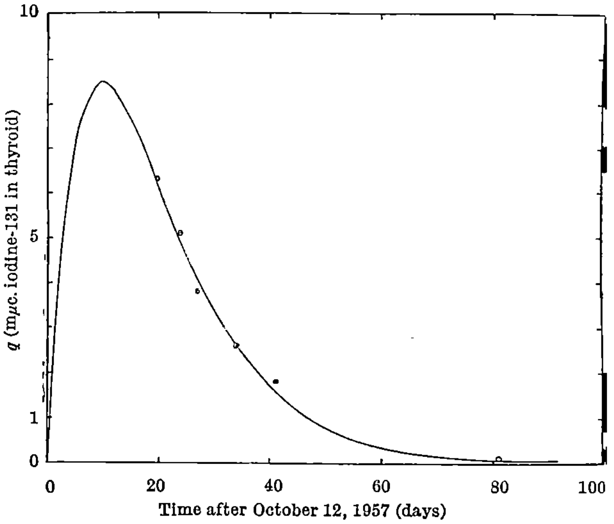

Fig. 1. Uptake and excretion of iodine-131 in human thyroid following the accident at Windscale. The curve represents the equation $q = 2{\cdot}3t \exp(-0{\cdot}1t)$; ●, experimental determinations on subject *H*

If we assume the same pattern of uptake throughout the group, then it is evident from the results in Table 1 that the average person in the Surrey and London groups received about one-third of this value, or 0·04 rad. The error, due to neglecting the possibility of initial 'build-up of activity in milk, should be small. An estimate of the upper limit of thyroid dose may be made by assuming—quite unrealistically with regard to the fact that milk contained iodine-131 at the time of the measurements—that this accident was due to a single intake of iodine-131 on October 11, when the main cloud passed over London. Then assuming that the half-period for decay thereafter was that expected for normal people[4], 7·5 days, since the mean level of iodine-131 in the London and Surrey group was about 2 mμc. on October 31, it may be shown that the total mean dose to the thyroid was 0·08 rad, or about twice that estimated by the more likely conditions above. The two children, *F* and *G*, had the same milk supply and were drinking about the same quantity of milk daily as person *N*. The similarity of the results for these three individuals suggests that there is little difference in the uptake of iodine-131 into the thyroid at different ages. Therefore, because of the different thyroid weights, the dose to the children's thyroids was twice that to the adult's.

The magnitude of the radiation dose to adult human thyroids in the London and Surrey people measured was therefore comparable with that expected each year from natural background radiation which, for example, amounts to about 0·1 rad per annum in Leeds[5] and about 80 per cent of this value in Sutton[6].

PROGRESS OF CANCER RESEARCH

THE current annual report of the British Empire Cancer Campaign for 1957* consists of a volume of more than 500 pages plus a supplement of 156 pages.

During the year the Campaign financed cancer research by grants of more than £600,000 ; the index of research workers mentioned contains nearly 1,100 names. Some idea of the type of research described in the report can be gained from Table 1, which divides up the different studies into a number of manageable groups. Any such classification is certainly liable to over-emphasize some lines of work and under-estimate the importance of others, but there seems no other way of indicating, however approximately, their relative attraction for those engaged in cancer research.

This table presents a puzzling aspect of cancer research, for why is it that the most interesting topic to-day, namely, smoking and lung cancer, is at the bottom of the list and not at the top ?

The report has the virtue of enabling the specialist to keep *au courant*, year by year, with what other workers in his field are doing ; but for other kinds of reader the report will prove heavy going, for it resembles, more and more, a catalogue of highly technical abstracts on abstruse subjects. This difficulty of reporting cancer research has developed partly because financial and other facilities have increased very rapidly, the result being to encourage expansion, not directly on cancer but on subjects which are somewhat indirectly related to it and are more amenable to investigation.

A further function of a report such as this is the necessary one of showing that the many and various recipients of Campaign grants have used those grants to good advantage. To do this, it is arranged geographically, according to the place where the work is done, and not by subject. But it must be recognized that the scientific value of the volume is much diminished by this. How much more striking a survey of progress in cancer research this could be made if work in each field was gathered together in even the roughest of logical orders. If that is impossible, is it too much to ask again for a subject index ?

Table 1. THE RELATIVE NUMBER, VERY APPROXIMATELY, OF INVESTIGATIONS DESCRIBED IN THE ANNUAL REPORT OF THE BRITISH EMPIRE CANCER CAMPAIGN FOR 1957

Radiation therapy ; radiobiology, radioisotopes	38
Carcinogens ; carcinogenesis	29
Nucleoproteins	27
Biochemistry of tumours ; cytochemistry and cytology	20
Hormones ; steroids	19
Clinico-pathology	20
Chemotherapy	12
Viruses ; fowl tumours	10
Immunology	8
Mutagens ; genetics	8
Tissue culture	6
Demography ; statistics	5
Smoking and lung cancer	5

The supplement (156 pages) to the report is by the veteran epidemiologist-statistician, Dr. Percy Stocks ; it is an account of his monumental study, "Cancer Incidence in North Wales and Liverpool Region in Relation to Habits and Environment", and is composed of sections on local differences in death-rates ; morbidity-rates ; urban and rural residence ; Welsh and Irish parentage ; marital history ; dietary histories ; smoking and smoke ; soil ; other factors (use of oil lamps ; use of petrol lighters ; streptococcal infections ; vaccination against smallpox ; residence in house with vegetable garden) ; national and vital statistics.

An interesting line of approach to the problem of chemical carcinogenesis is the persistent effort by the Birmingham group under Orr to prove that the primary lesion in carcinogen-induced skin carcinoma in the mouse is in the dermis, not the epidermis. The great majority of serious attempts to explain cancer begin by assuming that the essential change occurs in the cells which are proliferating and invading—in the malignant cells themselves. Indeed, the phenomena of metastasis and transplantation, where malignant cells clearly establish themselves of their own initiative in normal tissues, can scarcely be explained otherwise. Yet there have been many who have suggested that the changes seen in the stroma around early carcinomata (they are often conspicuous, especially in skin tumours) are more important than those in the epithelium. There has been little except equivocal histological evidence for this view in the past, but the experiments of the Birmingham group put it on a firmer basis. Their principal earlier experiments were simply of this type: mouse skin was painted with methylcholanthrene in carcinogenic doses, and then, before tumours developed, grafts were exchanged between painted and non-painted areas. If the grafts were made of pure epithelium by the Billingham–Medawar trypsinization technique, more tumours appeared in areas where normal epidermis had been grafted to a painted site than where painted epidermis was grafted to a normal site. Though there are several possible sources of error in these experiments, *a priori* they indicated the possibility that stromal changes in the graft-bed were important. The newer experiments have similar implications. Pure epidermal grafts implanted subcutaneously with crystals of methylcholanthrene do not, they report, give rise to tumours. On the other hand, if pellets of methylcholanthrene are implanted subcutaneously into mice, removed after as little as two weeks, and replaced by a small Thiersch graft of skin, squamous carcinomata appear. Yet the amount of hydrocarbon remaining at the site of the pellet after its removal is far below a normal carcinogenic dose. The evidence that in these experiments some stromal change is a major factor in carcinogenesis would seem on the face of it to be hard to deny. However, ovarian transplantation experiments reported in another connexion from the same school, but involving the same principle, gave results less uncomfortably at variance with accepted theories.

---

* British Empire Cancer Campaign. Thirty-fifth Annual Report covering the year 1957. Part 1 : The Chairman's Statement and the Accounts. Pp. xl. Part 2 : The Scientific Report. Pp. xli+528. Supplement to Part 2 : Report by Percy Stocks on Cancer Incidence in North Wales and Liverpool Region in Relation to Habits and Environment. Pp. iv+156. (London : British Empire Cancer Campaign, 1958.)

It is noteworthy that none of the Campaign laboratories engaged in the cigarette–bronchial cancer problem has yet succeeded in producing tumours experimentally with any substances derived from tobacco; yet the statistical evidence for the association is further increased by several contributions.

The report of progress made at the Westminster Hospital towards a possible treatment of leukæmia by irradiation and marrow replacement is disappointingly brief. Three cases have had irradiation to ilea and upper femora, sufficient to suppress their marrow content, followed by grafts of normal marrow from donors injected into the lower abdominal aorta; steroids and nitrogen mustard were also given. It is reported that evidence of successful establishment of the homograft marrow was obtained in two cases.

Much work is in progress on the fashionable homotransplant-immunity theory of cancer; but judgment must be suspended on most of it for the present. One of the most interesting (though perhaps the one least directly related to cancer) is an admirable brief account of Billingham's work on the 'runt' disease of mice. It will be remembered that new-born mice injected with spleen cells of a donor strain become tolerant to grafts from the donor strain in later life, but that, with many strain combinations, the recipient mice fail to grow and show severe atrophy of all lymphoid tissues; this is thought to be due to an immune reaction by the donated graft cells against the host. In general, further experiments support this interpretation, but some discrepant findings have emerged. Buffy coat suspensions, which cannot be used for the passive transfer of homotransplant immunity, will produce runt disease. Bone marrow under some conditions can produce tolerance without runt disease, and experiments with F_1 hybrids have not altogether confirmed the results predicted.

The reports from physicists working on various forms of cancer research show that these workers fall into two main classes. In one group are those who concentrate on the physical aspects of biological problems and who are really becoming a race of biophysicists, and in the other are those who concentrate on improvements in the equipment and techniques used in this very wide field. These two main classes meet in the common field of radiation protection. The sensitive measuring techniques developed for this very essential service are now being put to investigating the various sources of natural radioactivity and its role in the possible production of malignant conditions.

One centre working on this problem has measured the natural radioactivity occurring in forty types of soils and fertilizers as well as hundreds of other environmental materials. A chalk pit has been excavated to form a low-activity counting area in which various substances including unprocessed milk have been assayed for isotopes such as cæsium-137 and iodine-131 which may be present. Theoretical studies have been made of the dosimetry of possible depositions of a beta-emitting isotope in bone. These calculations have been applied to the comparative dosage of radium and of strontium-90 when these elements are present under similar conditions. Total body counters are also being improved upon each year and a portable high-pressure ionization chamber has been developed which enables normal background dose-rates to be measured to an accuracy of ± 2 per cent in a measurement time of about 3 min. Studies of the 'rain-out' from tests of nuclear weapons exploded at Maralinga have been continued. Clear evidence of the presence of artificial radioactivity in rain 18 hr. after the explosions has been obtained. More definite information has been collected from measurements on rain which fell up to 14 days later.

Radioactive isotopes are now being widely used as a routine research tool, and many refinements of existing counting techniques are reported. Most of these modifications are designed to increase the sensitivity so as to enable lower levels of radioactivity to be used for *in vivo* studies. At the opposite end of the scale, large amounts of radioactive isotopes such as cobalt-60 and cæsium-137 are being used for the treatment of malignant diseases, and measurements have been made of the dosage distribution from a source of 1,150 c. of cobalt-60.

Reading this report as a whole leaves one with the impression that research in the field of cancer, as in most other fields, is becoming steadily more of a team project in which each member of the team needs to know a little of all the other aspects as well as a lot about his own. Physicists working on biological problems need to have a wide knowledge of biology, and biologists using physical techniques and methods nowadays require a grounding in physics to enable them to get the best interpretation of the data obtained using present-day equipment and to suggest possible modifications of such equipment for their particular problems.

OBITUARIES

Dr. Felix Oswald

Dr. Felix Oswald, a distinguished geologist and archæologist, died on November 3 on the ninety-second anniversary of his birth in 1866.

After gaining the degree of B.A.(London), Oswald entered the Civil Service. In his spare time, however, he made a study of geology, botany and zoology, and eventually presented these as his subjects for the B.Sc. degree examination, London, in which he gained first-class honours.

In 1898 he accompanied N. B. Lynch as geologist on a tour through Turkish Armenia. On their arrival at Lake Van, he made a careful investigation of the rocks and structure of the Crater of Nimrud, a volcano on the west shore of the lake. He later wrote "The Geology of Armenia" and presented it as his thesis for the degree of D.Sc.(London). As the cost of providing the requisite number of copies for the examiners proved prohibitive, he set up a press and printed 200 copies himself. The book had 600 pages and a number of coloured illustrations. He also made a geological map of Armenia and a coloured relief model of the Crater on the scale of 1 in. to the mile.

In 1907 he was elected a Fellow of the Geological Society of London. He also received from the Council of the Society an award from the Murchison Fund in recognition of his work in Armenia. In 1911 he went to Central Africa, on behalf of the British Museum, to investigate fossiliferous beds of Mid-Tertiary Age that had been discovered north-east of Victoria Nyanza. Four years later he was sent to the Caucasus in response to a request from the Russian Government for a geologist to search that region for additional sources of oil. In this work he was successful, and in addition produced a geological map of the Caucasus mountains.

Meanwhile, Oswald was appointed probate registrar for the East Midlands and accordingly moved to Nottingham. Here he became interested in Margidunum, a Roman station situated on the Fosseway. About 1911 he started excavating the site and continued until his retirement, in 1936, to Solva in Pembrokeshire. He built up a remarkable collection of pottery from the site. This is now housed in the museum of the University of Nottingham. He visited every important collection of Roman pottery in Europe. With the unrivalled knowledge thus gained, he produced several magnificent works on terra siggillata and many small ones, including detailed accounts of Margidunum. He won an international reputation, and even during his long retirement was visited and consulted by scholars from many parts of the world.

H. H. Swinnerton

Dr. Francisco Duran-Reynals

The death of Dr. F. Duran-Reynals, which occurred on March 27, 1958, deprived experimental pathology of one of its outstanding figures. Apart from many well-known studies of the role of viruses in the etiology of cancer, I particularly wish to record Duran-Reynals's influence—not so widely appreciated—in stimulating this field over many years less directly, and in encouraging developments which in turn have facilitated recent dramatic advances, particularly in the United States, in our knowledge of tumour viruses.

Francisco Duran-Reynals was born in Barcelona on December 5, 1899. After graduating from the University of Barcelona as M.D. in 1925, he then spent three years in work at the Pasteur Institute in Paris (with Profs. A. Besredka and E. Wollman), and (with Dr. J. B. Murphy) at the Rockefeller Institute, New York, to the staff of which he was appointed in 1928. In 1938, he became research professor at Yale University School of Medicine, with support from the Jane Coffin Childs Memorial Fund for Medical Research.

Duran-Reynals's earlier work was mainly concerned with the so-called ground-substance of the mesenchyme, and arose from the discovery of spreading factors—hyaluronidase and others—in mammalian testes (1928), bacteria (1933), snake venom (1936), and many other sources. His studies of viruses in relation to cancer date from 1938, and were continued to the end of his life, with much assistance from his wife, M. L. Duran-Reynals. These studies bore specially upon such aspects as virus variation and adaptation, antigenicity and epidemiology, and an important observation (of particular interest in relation to more recent discoveries) was of their maximal infecting power when injected into immature hosts.

Duran-Reynals was the recipient of many honours, notably (in 1952) the Anna Fuller Memorial Prize for Medical Research. His contributions not only to the above problems but also to many others in experimental pathology are embodied in upwards of a hundred papers, the last (1958) being a study of the infectious pulmonary adenoma complex in sheep.

In all he did he was not only scientist but artist as well. None who had the privilege to know him will soon forget his endearing qualities, his courage and gaiety, or his love of his native Spain.

A. Haddow

Dr. R. C. Fisher

Dr. Ronald Campbell Fisher was born on August 6, 1899, at Edinburgh, and died unexpectedly in his sleep on October 23. He was the elder son of Archibald W. Fisher, solicitor, and Catherine Dick Fleming. From George Heriot's School he proceeded to the University of Edinburgh, where he graduated in forestry in 1921 and was awarded the medals for advanced forestry and forest zoology. Following studies at Kew and Rothamsted on a research scholarship awarded by the Ministry of Agriculture and Fisheries, he received his doctorate for a thesis on forest insects in 1923.

After working for two years at the Imperial Forestry Institute, Oxford, Fisher transferred to the Forest Products Research Laboratory (Department of Scientific and Industrial Research) at Princes Risborough, as the first officer-in-charge of the Entomology Section. At that time, little was known of timber-boring insects in Great Britain, but during the thirty-one years he was in charge of this work, he published, or was the co-author of, more than sixty papers and H.M. Stationery Office publications on this group of insects, and his staff published many more. His main contribution to the literature was the four papers which he published in the *Annals of Applied Biology* under the title of "Studies in the Biology of the Death Watch Beetle". These papers, and those of the late W. G. Campbell (officer-in-charge, Wood Chemistry Section, Forest Products Research Laboratory) on the nutritional aspects of this species, formed a basis for improved control measures in the light of the knowledge revealed on the association between death watch beetle attack and preceding fungal decay. For his paper on "Recent Work on Wood-Destroying Insects" he received a silver medal from the Royal Society of Arts. He read his last paper, entitled "Developments in the Control of Timber Insects", before the Society of Chemical Industry only three days before his death.

During his years at the Forest Products Research Laboratory, Fisher was constantly consulted on problems concerning wood-boring insect infestations, not only in timber, joinery and furniture, including many of the ancient buildings of historical interest in Britain, but also on infestations of tropical timbers. A physical disability had prevented him from following the career of a forest officer, but he retained a keen interest in the entomological problems of forest insects and in particular of the *Ambrosia* beetles. The post-war shortage of traditional timbers and demand for substitutes from among tropical species brought the *Ambrosia* beetle problem to the fore, and it was mainly due to his efforts that the West African Timber Borer Research Unit was set up by the Colonial Office in 1952. The supervision of the training of the staff of this unit and their research programme became one of his chief interests. He also served on H.M.S. *Victory* Technical Advisory Committee and on the committee set up by the Central Council for the Care of Churches. He was elected a Fellow of the Royal Society of Edinburgh in 1952.

He leaves a wife and two sons of whom the elder, Dr. R. Campbell Fisher, is studying insect parasites at the Entomological Laboratory, Belleville, Ontario, Canada, and the younger, aeronautical engineering at the University of Bristol. J. D. BLETCHLY

NEWS and VIEWS

Atoms for Peace Award:
Prof. G. C. de Hevesy, For.Mem.R.S.

THE second Atoms for Peace Award of 75,000 dollars and a gold medallion, founded as a memorial to Henry and Edsel Ford, has been made to Prof. G. C. de Hevesy, associate of the Institute for Research in Organic Chemistry, University of Stockholm, and of the Institute of Theoretical Physics, Copenhagen. In announcing the award, Dr. Detlev Bronk, president of the Rockefeller Institute for Medical Research and of the U.S. National Academy of Sciences, said that Prof. Hevesy was selected unanimously from 111 nominations for "his basic contribution to the peaceful uses of atomic energy in the discovery and development of tracer techniques in chemistry, biology, and medicine, using natural and artificial radioactive and stable isotopes for his continuing work in these fields". Prof. Hevesy is a Foreign Member of the Royal Society and was awarded the Copley Medal in 1949. He received the Nobel Prize for Chemistry in 1943.

United States Atomic Energy Commission:
Dr. Frank K. Pittman

DR. FRANK K. PITTMAN has been appointed director of the Division of Reactor Development of the U.S. Atomic Energy Commission, and the functions previously assigned to the Office of Industrial Development have been transferred to that Division, except for those having to do with isotope development. The functions of isotope development will be undertaken by an Office of Isotope and Radiation Development with Dr. Paul C. Aebersold acting in charge.

Dr. Pittman graduated at Vanderbilt University and received his Ph.D. in inorganic chemistry from the Massachusetts Institute of Technology. He has been associated with the United States atomic energy programme since 1944, when he joined the staff of the Los Alamos Scientific Laboratory. He was in charge of plutonium production at the Laboratory until 1948. He has been director of the Office of Industrial Development since it was established in December 1957, and also had been serving as acting director of the Division of Reactor Development since August 5, following the resignation of W. Kenneth Davis.

Smith Kline and French Research Institute:
Prof. W. A. Bain

PROF. W. A. BAIN, who has held the chair of pharmacology at the University of Leeds since 1946, has accepted an invitation to become director of the Smith Kline and French Research Institute, and will resign his university appointment to take up this new post. After graduating in Edinburgh, William Alexander Bain became assistant to the late Sir E. Sharpey Schafer in 1928. In 1931, he was appointed lecturer in experimental physiology in the University of Edinburgh, before moving to Leeds in 1934, where he became, first, lecturer in physiology and later reader in pharmacology. Prof. Bain has conducted research on the autonomic nerves, on adrenaline and on the antagonists of histamine.

Laboratories for the Smith Kline and French Research Institute are under construction at Welwyn Garden City and are expected to be completed by the late summer of 1959. The research team which Prof. Bain will direct will form an important part of, and be complementary to, the extensive research effort of the parent company in Philadelphia. The Company believes that by having research teams both in Great Britain and in the United States there will be advantages to both by the interplay and exchange of scientific fact, opinions, outlook and approach.

Bell Telephone Laboratories: New Directors of Research

DR. W. D. Lewis, of Mendham, and Mr. A. H. White, of Summit, have been appointed directors of research at Bell Telephone Laboratories, Murray Hill, New Jersey. Dr. Lewis will be in charge of research on switching and transmission systems and techniques. Mr. White will be director of research in the physical sciences, including physics, chemistry, semiconductors, solid state electronics, metallurgy and materials. With Dr. J. R. Pierce, formerly director of research in electrical communications and now director of research in communications principles, Dr. Lewis and Mr. White will report to Dr. W. O. Baker, vice-president in charge of research.

Commonwealth Co-operation in Scientific Research

In the course of a speech on October 20 when opening the Esso Research Laboratories at Abingdon, the Lord President of the Council, Viscount Hailsham, referred to our comparative neglect of research as a nation, to which we devoted far too little of our resources, and emphasized the role of industry and the universities as well as of the Government. He said that in the view of the Government it was most important that there should be available in the Commonwealth, for those members who needed it, advice and assistance from other members including the United Kingdom, wherever these were available and funds could be found to meet it. Accordingly, the Government had announced at Montreal that, under the general control of the Committee of the Privy Council, an Overseas Research Council would be set up concerned with scientific research overseas, particularly in the Commonwealth (*Nature* of November 22, p. 1413). Our existing organizations in industrial, medical, and agricultural science would be available to give assistance through this new body, and he hoped new and fruitful scientific links would be formed in this way between Great Britain and members of the Commonwealth. Secondly, Lord Hailsham welcomed the attention which the United States was giving to research in the tropics, and particularly in Africa, as a fruitful field for Anglo-American co-operation (*Nature* of November 8, p. 1276).

The Institute for Strategic Studies, Ltd.

The formation of the Institute for Strategic Studies, Ltd., for the study of defence and disarmament has been announced. The Institute will be international, but the headquarters will be in London. Mr. Alastair Buchan, formerly defence and diplomatic correspondent and now assistant manager of the *Observer*, has been appointed director. The purpose of the Institute is to provide a focus for the study and discussion of the effects of political and scientific developments upon strategy, Western defence policies, and disarmament plans. It is also intended to develop a reference centre. The Ford Foundation in New York has made a grant of 150,000 dollars to finance the Institute for the first three years.

The founder members of the council of the Institute are: Sir Kenneth Grubb (chairman, Commission of the Churches on International Affairs) (*chairman*), Mr. Richard Goold-Adams (*vice-chairman*), Lord Salter (*honorary treasurer*), Prof. P. M. S. Blackett (professor of physics, Imperial College of Science and Technology), the Rev. Alan Booth (secretary, Commission of the Churches on International Affairs), Rear-Admiral Sir Anthony Buzzard (director, Vickers-Armstrongs, Ltd.), Air Chief Marshal Sir Ronald Ivelaw-Chapman, Lieutenant-General Sir John Eldridge, Mr. Kurt Hahn (former headmaster, Gordonstoun and Salem Schools), Captain B. H. Liddell Hart, Sir William Hayter (warden of New College, Oxford), Mr. Denis Healey, M.P., Mr. Michael Howard (lecturer in war studies, King's College, London), Sir James Hutchison, M.P., Lord McNair, Marshal of the R.A.F. Sir John Slessor. Sir Henry Tizard, Mr. Donald Tyerman (editor of the *Economist*), Canon H. M. Waddams (secretary, Church of England Council on Foreign Relations), Lord Weeks, and Mr. C. M. Woodhouse (director-general, Royal Institute of International Affairs). The Institute will also have an international advisory committee on strategy, defence, and international affairs throughout the Free World.

Committee of Public Accounts: Report for 1957–58

In its third report for the session 1957–58 (pp. 32. London: H.M. Stationery Office, 1958. 1*s*. 6*d*. net) the Committee of Public Accounts admits that the evidence given to the Committee last session regarding the cost of construction of the Jodrell Bank radio telescope was gravely inaccurate and misleading. The accounting officer now states that he is satisfied, after discussing the matter with the University of Manchester, that there was extensive consultation between the consultant engineers and the professor in charge on questions of design. There was, in fact, the fullest collaboration on scientific and technical matters between the consultants and the professor, and accordingly the concern expressed by the Committee in its third report for the session 1956–57 is essentially unfounded. It is, however, still not satisfied with the financial control exercised over this scheme, either by the Department or by the University, and welcomes the Treasury minute on its previous report indicating that steps are being taken to ensure close control by both the university and the Government department concerned in any future case of this kind. The Treasury has now authorized payment of an additional grant of £130,000, making a total of £560,000, and the Committee welcomes the assurance that the balance of the expenditure for the construction of the telescope will be found from other sources by the University (*Nature*, November 29, p. 1484).

United States Euratom Agreement

An agreement for co-operation in the civil uses of atomic energy between the United States and Euratom was signed on November 8 in Brussels. The major objective of the agreement is to bring into operation in the Community in the next five to seven years approximately one million electrical kilowatts of nuclear power capacity, using reactor types developed in the United States. It is expected that the provisions for wide dissemination of information under the programme will provide industrial organizations in the Community and the United States with valuable engineering experience, and technological and economic data concerning the operation of nuclear power plants in Europe under conditions that will be nearly competitive with conventionally fuelled plants. The capital cost of the joint nuclear power programme, exclusive of fuel, is expected to be about 350,000,000 dollars. An integral part of the programme is a joint ten-year research and development project. During the first five years the Community and the United States will each contribute up to 50,000,000 dollars. Before the expiration of the first five years the participants will determine the financial requirements for the remaining five years and will undertake to procure the necessary funds for the programme.

Committee on Space Research

At its recent meeting in Washington the International Council of Scientific Unions established a Committee on Space Research (COSPAR), with the primary purpose of providing a means whereby the scientific community may use to maximum advantage the possibilities of satellites and space probes for scientific purposes, and exchange the results on a co-operative basis. On November 14 and 15 the Committee on Space Research held its first meeting in the rooms of the Royal Society in London. A constitution was drawn up for approval by the International Council of Scientific Unions, and the following executive committee was elected: *President*, Prof. H. C. van de Hulst (International Astronomical Union); *Vice-Presidents*, Prof. E. K. Fedorov (U.S.S.R. Academy of Sciences, Moscow), Prof. W. Albert Noyes, jun. (University of Rochester, New York); *Members*, Prof. Maurice Roy (International Union of Theoretical and Applied Mechanics), Prof. H. S. W. Massey (International Union of Pure and Applied Physics).

National Science Foundation Grant for U.S. National Observatory

The National Science Foundation has allocated 4 million dollars to the Association of Universities for Research in Astronomy, Inc. (AURA), for the construction of a solar telescope. These funds bring to a total of 7,545,000 dollars the amount that has been allocated so far for the erection and operation of a United States national astronomical observatory on Kitt Peak in the Quinland Mountains of south-western Arizona (see *Nature*, 181, 236; 1958). An additional 1 million dollars has been appropriated by Congress to the National Science Foundation for transfer to the Bureau of Public Roads for construction of a road giving access to the observatory site, which has been leased from the Papago Indians, in whose reservation it lies.

The solar telescope will be equipped with an 80-in. light-gathering flat at the top of the tower, and a 60-in. image-forming mirror, with a focal length of 300 ft. The instrument will thus be the largest solar telescope in existence, with about twice the focal length of the famous 150-ft. tower telescope at Mount Wilson. Stellar instruments at the observatory will consist initially of a 36-in. reflecting telescope to be made by Boller and Chivens, of South Pasadena, California, and an 80-in. high-speed reflecting telescope by Corning Glass Works, with auxiliary instrumentation.

Lunar Topography: Gift to the University of Manchester

The Geophysics Research Directorate of the U.S. Air Force, Cambridge (Mass.) Research Center, entered, as from November 1 of this year, into a contractual arrangement with the University of Manchester (through the European Office of the Air Research and Development Command in Brussels) to support in its Department of Astronomy an extended programme of topographic studies of the Moon. This emphasizes the current need for more accurate information on the heights and dimensions of lunar surface features than we possess to-day. A large part of such data as are now available go back to the work of amateur astronomers of the nineteenth century, and are based on visual measurements the accuracy of which leaves much to be desired. The Department of Astronomy at Manchester, under Prof. Zdeněk Kopal, proposes to increase this accuracy by filming sunrise or sunset over selected lunar regions, and triangulating for the topographical details of the landscape from measurements of the varying lengths of the shadows. This work was actually commenced two years ago by collaboration between the University of Manchester and the Observatoire du Pic-du-Midi in the High Pyrenees, which is well known for its superior seeing, and the photographic work done through the 24-in. refractor of the Observatory by kind permission of the director, Dr. Jean Rösch. The measurements and reductions of all films are to be made at Manchester under the supervision of Dr. Gilbert Fielder.

The ciné technique, pioneered by R. R. McMath, R. M. Petrie and H. E. Sawyer at the University of Michigan in the middle 1930's, has been elaborated in recent years at Manchester and has attained new standards of precision; its application to the Pic-du-Midi photographs makes it possible now to distinguish, on the Moon, objects of linear dimensions in excess of 500 yd., and altitude differences of the order of 20–30 yd. The programme of mapping the entire visible hemisphere of the Moon to this accuracy will probably occupy the Department of Astronomy at Manchester for the next five years, at a total cost of approximately 80,000 dollars.

Rowan Hamilton Bridge

On November 13, Mr. Eamon de Valera, Prime Minister of the Republic of Ireland, unveiled a tablet on Broome Bridge at Cabra, Dublin, to commemorate the invention of quaternions. The bridge has now been renamed Rowan Hamilton Bridge. The story of Hamilton and his bridge ranks with those of Archimedes and his bath and of Newton and his apple, as the Provost of Trinity College (Dr. A. J. McConnell) remarked in his speech at the ceremony, and it concerns a man of comparable intellectual stature. On October 16, 1843, Sir William Rowan Hamilton was walking with his wife along the Royal Canal from Dunsink Observatory to preside at the Council of the Royal Irish Academy when, on coming to Broome Bridge, the long-sought fundamental rules for quaternion algebra flashed upon his mind. Acting upon what he afterwards called an "unphilosophical impulse", he scratched the formulæ on the stonework with his penknife. The same afternoon he gave notice of his intention to read a paper on the subject at the Academy meeting on the following November 13—hence the date chosen for the unveiling. The tablet was erected by the Council of the Dublin Institute for Advanced Studies, of which the Right Rev. Monsignor P. Browne is chairman. Mr. de Valera, who is himself a mathematician well versed in Hamilton's work, has taken a keen personal interest in the project, which was carried on under the active direction of Prof. F. E. Hackett, chairman of the Governing Board of the School of Theoretical Physics of the Institute.

Hamilton's work on quaternions had widespread influence upon the development of mathematics, especially in America, and it was a pioneering step towards the subsequent far-reaching enlargement of algebra. While it is Hamilton's work in other fields that has had such a profound influence upon the whole form of modern theoretical physics, it would be scarcely possible to find in it, or in the work of any other theorist, anything more apt or evocative for a public memorial than the episode that has now been commemorated. The memorial in Dublin may be unique as one commemorating a particular discovery in mathematics, and must surely be unique as one inaugurated by the head of a Government who personally appreciates the significance of an achievement of this kind.

British Museum (Natural History): The Hedges Collection of British Moths

Among the more important acquisitions recently reported to the Trustees of the British Museum (Natural History) was the Alfred Vander Hedges collection of British moths presented by Mrs. Celia Hedges, in accordance with the wish of her late husband. The collection is a very extensive one, comprising about 20,000 specimens, and consists almost exclusively of specimens reared in captivity by Mr. Hedges. Some of the specimens had been reared in experiments in connexion with genetical studies in co-operation with the late Dr. E. A. Cockayne, whose collections are already the property of the Museum. Others are the result of his intensive collecting in the Isle of Man, as a consequence of which many species previously unknown in that Island were discovered to be present. The whole collection is in the most perfect condition.

The National Trust

The sixty-third annual report of the National Trust presented to the annual meeting on November 7 records a further increase of membership to 70,687 during the first five months of the year, but the figure is still short of the 100,000 the Council hopes to reach by January 1960, and only a membership consonant with its responsibilities can enable the Trust to exert its full influence for the preservation of the best of the countryside and Britain's finest buildings. The report refers to the need to dispel widespread misapprehension arising from the title 'National Trust', which tends to obscure the Trust's dependence on voluntary support. Emphasis is also placed on the changes in method which the Trust has had to adopt now that it is increasingly concerned with the impact of the public on the countryside. Its duty has often become one of control to preserve the countryside from damage by litter hooliganism or even the sheer wear of numbers on a limited area. The Trust has had to face unpopularity in some quarters in confining the public to footpaths on agricultural land, in strictly limiting caravans, tents and car parks to appropriate sites, and generally in regulating access to its open spaces. Certain changes in the administration of the Trust are being made in accordance with the recommendations of a special committee appointed to consider the subject, and the first regional secretary has been appointed. The Trust's nature reserves continue to prosper and are becoming increasingly important. The new mere at Wicken Fen has already attracted a large variety of ducks and waders; the eider is again breeding in the Farne Islands in ever-increasing numbers and 600 pairs of Sandwich terns are known to have nested at Blakeney, while figures for redshank and little tern were also well above the average.

Forest Products Statistics

With the completion of the decade of publication of the Yearbook of Forest Products Statistics, the Forestry Division of the Food and Agriculture Organization of the United Nations has decided that in view of the considerable progress that had been achieved in making the compilation more complete, more uniform and more accurate, it would be of value to revise the earlier issues, bringing the data as nearly in line as possible with the latest, and to publish a ten-year summary. The particular value of such a summary (World Forest Products Statistics: a Ten-Year Summary, 1946–1955. Pp. viii+197. Rome: Food and Agriculture Organization; London: H.M. Stationery Office, 1958. 15*s.*; 3 dollars) lies in its use for the study of trends, which have become so important with the rapid developments in production and use of timber in most parts of the world.

This development is continually in progress and is exemplified in the Yearbook for 1957 (Pp. vi+169. Rome: Food and Agriculture Organization; London: H.M. Stationery Office, 1957. 12*s.* 6*d.*; 2 dollars) by the provision of separate statistics for particle board (defined as a board "constituted from fragments of wood and/or other vegetable materials which have been comminuted and then consolidated by pressure, heat, etc., with or without binders and supplementary materials"). World production of these materials rose from less than 500,000 metric tons in 1955 to 705,000 metric tons in 1956, more than half being in the United States and Germany, and there is every indication that there will be continued expansion in the future; there are factories in the United Kingdom, but the total output is still small. Another change in this issue is the inclusion of estimates for the relatively few countries from which returns have not been received; without these, regional totals can be very misleading.

Progress in Geology

The present century has, perhaps, been more notable for advances in techniques and in the accumulation of detailed knowledge than in the formulation of radically fresh ideas in geology, and it is of interest to inquire what general trend is discernible in the interpretation of the Earth's history as a result of these advances. Prof. L. Hawkes, in his anniversary address to the Geological Society of London (*Quart. J. Geol. Soc.*, 133, 309; 1958), considers that vindication of the Lyellian doctrine of uniformitarianism has been the central theme of progress in geology in the past fifty years. During this period determination of the age of minerals by radioactive decay methods has underlined the immensity of the geological time-scale. At the same time, precise geodetic measurements have disclosed crustal movements in various parts of the world to-day proceeding at rates which, bearing this time-scale in mind, are adequate to account for the huge deformations of the past, thus extending the principle of uniformitarianism to the field of tectonics. Not only must earlier ideas on the catastrophic nature of mountain-building processes be discarded, but the presumed world-wide synchronism of mountain-building periods may also be seriously challenged as isotopic methods of dating and correlating sediments are improved. There may be no 'pulse of the Earth'. Normal sedimentary rocks were being formed at least 3,000 million years ago, and there is now direct fossil evidence for the existence of simple forms of life more than 2,000 million years ago. Conditions on the Earth's surface seem to have been much the same as they are to-day over a much longer span of time and in more ways than would generally have been believed possible fifty years ago.

Science Masters' Association

THE annual meeting of the Science Masters' Association is to be held in University College, Gower Street, London, W.C.1, during December 30–January 2. The programme includes the following lectures: "The Scope of Modern Physics", by Prof. H. S. W. Massey; "Principles of Organic Chemistry", by Prof. E. D. Hughes; "Algal Pigments", by Dr. G. E. Fogg; "Industrial Applications of Radioisotopes", by J. L. Putman; "Learning in Octopuses", by Prof. J. Z. Young; "Opportunities for Students in Colleges of Technology", by Dr. J. Topping; "Old Metals and New Valencies: the Stabilization of Unusual Valency States", by Prof. R. S. Nyholm; "Techniques in Nuclear Physics", by Dr. E. H. S. Burhop; "New Engineering Problems in Aeronautics", by H. G. Conway; "The Study of Ripples by the Schlieren Method", by W. Llowarch; "Molecular Spectra and Molecular Structure", by Dr. D. J. Millen; "Some Problems in Teaching Science in Large Secondary Schools", by R. J. Scammell. Accommodation for members at the meeting will be provided at Queen Elizabeth College, Kensington, W.8; Canterbury Hall and Bentham Hall, both in Cartwright Gardens, W.C.1. Further information can be obtained from the annual meeting secretary, Mr. W. H. Dowland, 93 Westbourne Road, West Hartlepool, Co. Durham.

Imperial Chemical Industries Transfer Scholarships

LAST year, thirty-three university students who decided that they wanted to change from the arts to science were able to do so by taking advantage of the Imperial Chemical Industries transfer scholarship scheme. Most of these students have now passed their examinations and have entered their chosen science honours school. Of the twenty-seven transfer scholars elected in 1956, more than 80 per cent successfully made the change from arts to science. These encouraging figures have persuaded Imperial Chemical Industries to extend its guarantee of scholarship funds for a further two years to the universities which originally co-operated in the scheme. These are Oxford, Cambridge, Liverpool, Imperial College of Science and Technology, London, and King's College, Newcastle. At Oxford the number of scholarships available will be extended so that, in common with Cambridge, every college will have a transfer scholarship in its gift. Scholarships not taken up can be passed on to other colleges which have more than one suitable candidate. In all, sixty-five of these scholarships are now available, the universities co-operating also including Birmingham, Bristol and Sheffield, which came into the scheme a little later.

University News: Belfast

THE following appointments have recently been made: Dr. C. L. Wilson, to a personal chair in analytical chemistry; Dr. R. B. Welbourn, to a personal chair in surgical science; Dr. P. J. B. Clarricoats, to a lectureship in light electrical engineering; Dr. P. C. Elmes, to a lectureship in therapeutics and pharmacology.

London

THE following have been appointed to University readerships in the subjects indicated: Mr. J. R. D. Francis, lecturer at the Imperial College of Science and Technology (fluid mechanics); Dr. R. W. Tiffen, lecturer at Birkbeck College (applied mathematics); Mr. W. J. Tulley, lecturer at Guy's Hospital Medical School (orthodontics). Dr. Emrys Jones, lecturer in geography at the Queen's University of Belfast, has been appointed to the University readership in social geography tenable at the London School of Economics and Political Science.

Announcements

THE Christmas Lecture arranged by the Institution of Electrical Engineers will be held in the Institution's rooms on December 31, at 3 p.m., when Dr. E. R. Laithwaite (University of Manchester) will speak on "Invention and New Machines". Admission to the Lecture is by ticket, obtainable, free of charge, from the Secretary, Institution of Electrical Engineers, Savoy Place, London, W.C.2.

THE annual Christmas lectures organized by the Royal Photographic Society for a juvenile audience, which will be given in the Department of Photography at the Regent Street Polytechnic, London, W.1, at 2.30 p.m. on January 1 and 2, 1959, will be on "Picture Making in Photography". Tickets are free, and can be obtained on application to the Secretary of the Royal Photographic Society, 16 Princes Gate, London, S.W.7.

THE annual conference of the Geographical Association will be held in the London School of Economics, Houghton Street, London, W.C.2, during December 30, 1958–January 2, 1959. Further details can be obtained from the honorary conference organizer, Mr. R. C. Honeybone, University of London Institute of Education, Malet Street, London, W.C.1.

THE Palæontology Association will hold a discussion meeting on "Micro-palæontology" in the Department of Geology, Sedgwick Museum, Cambridge, on December 12 and 13. Sixteen papers on spores, ostracods, conodonts and foraminifera will be read, and there will also be a large number of exhibits. Further information can be obtained from Dr. Gwyn Thomas, Department of Geology, Imperial College of Science and Technology, London, S.W.7.

THE Physical Society is organizing a conference on "Problems of Collective Motion", to be held at the University of Birmingham, on January 2 and 3, 1959. Informal discussions will follow introductory talks on gaseous plasma; plasma problems in the electron theory of metals; liquid helium and superconductivity; and collective problems in nuclear dynamics. The conference is open to non-members of the Physical Society on payment of a fee of one guinea. Further information can be obtained from Miss E. Mills, Physical Society, 1 Lowther Gardens, Prince Consort Road, London, S.W.7.

THE following scholarships will be offered by the Institution of Naval Architects for competition in 1959: Denny Scholarships in Naval Architecture and Naval Engineering: £175 per annum, tenable for four years at the University of Glasgow, and open to British subjects less than nineteen years of age who have not yet begun an apprenticeship, or served not more than one year of it with Messrs. William Denny & Bros., Dumbarton. Parsons Scholarship in Marine Engineering: £175 per annum, open to British apprentices or pupils in marine engine works or the Royal Dockyards less than twenty-one years of age. Yarrow Scholarship in Marine Engineering: conditions as for Parsons Scholarship in Marine Engineering. Further particulars can be obtained from the Secretary, Institution of Naval Architects, 10 Upper Belgrave Street, London, S.W.1.

THE COMMONWEALTH SCIENTIFIC AND INDUSTRIAL RESEARCH ORGANIZATION, AUSTRALIA

CONSTITUTED in 1926 by Act of the Australian Parliament, the Council for Scientific and Industrial Research grew steadily and, in 1949, its name was changed to the Commonwealth Scientific and Industrial Research Organization. This led to little change in its policy and methods of work, the Organization being divided into a number of Sections and Divisions, each of which enjoys a large measure of autonomy in the conduct of its scientific programme. The Divisions and Sections cover a very wide field of scientific activity with the exception of atomic energy and human medical science; considerable activity is directed to veterinary science. The Organization is not a Government department, but is a Government 'instrumentality' which draws approximately 80 per cent of its revenue directly from the Treasury. The remainder is provided by other Commonwealth 'instrumentalities', such as the Snowy Mountains Authority, and certain industrial groups which finance investigations of interest to these bodies.

The work of the various Divisions and Sections is reflected in a remarkable series of publications, each of which does credit to an Organization which is very well administered and is doing so much for the development and spread of scientific inquiry throughout the southern hemisphere. These publications include journals, bulletins, technical papers, monographs, land research series and soil publication series.

Among the more special journals are the *Australian Journal of Physics*, the *Australian Journal of Chemistry*, the *Australian Journal of Applied Science* and the *Australian Journal of Biological Sciences*, each of which is issued quarterly; the *Australian Journal of Agricultural Research* is published six times a year. Not issued at regular intervals are the *Australian Journal of Marine and Freshwater Research*, the *Australian Journal of Botany* and the *Australian Journal of Zoology*. The *Journal of Biological Sciences* differs from the *Journals of Botany* and *Zoology* in paying more attention to the experimental sciences; the botany and zoology journals are more concerned with the descriptive phases.

The Australian Academy of Science co-operates with the Organization in maintaining appropriate standards in the eight journals mentioned above, and the journals are open to receive contributions from research workers, irrespective of country or of the establishment to which they are attached.

In a recent issue of the *Journal of Biological Sciences* (10, No. 4), for example, articles were included dealing with the physiology of pea fruits, with special reference to changes in sugars and phosphate compounds in the developing seed; the effects of auxins on the binding of pectin methylesterase to cell-wall preparations; the lag period in auxin-induced expansion of storage tissue and coleoptiles; the effect of developing embryos on plant viruses; studies on the seed transmission of plant virus diseases; the metabolism of *Ascaris lumbricoides* ovaries; the dose response to bovine plasma albumin in mice and the simulation of genetic systems by automatic digital computers.

A recent volume of the *Journal of Botany* (5, No. 2) contains descriptions of floral histogenesis in the Cyperaceae; the regeneration of severed pea apices; the soil moisture patterns produced by rainfall interception and stem-flow in Dark Island heath; the high mountain vegetation in Australia; and the nature and distribution of rain-forests in New South Wales.

The *Journal of Agricultural Research* is a medium for the publication of investigations relating to plants, soils and domestic animals, covering the physical, chemical and biological aspects in this field. Examples of the wide range of topics investigated is shown by a list of topics taken from a number published some months ago (8, No. 6). The topics included air-tight storage of grain and its effects on insect pests; the pruinose scarab (*Sericesthis pruinosa* Dalman) and its control in turf; the renovation of *Phalaris* pastures with special reference to nitrogen and sulphur relationships; quantitative inheritance in lucerne with particular reference to winter yield; a comparison of three low-persistence viruses of the strawberry; the effect of volatile fatty acids, lactic acid, and ammonia on rumen *p*H in sheep; the effect of diet on individual volatile fatty acids in the rumen of sheep, with particular reference to the effect of low rumen *p*H and adaptation of high-starch diets; the tolerance of sheep to sodium chloride in drinking water; a study of wool production per unit area of skin in Australian merino sheep; the equatorial light environment and its effect on the coat of European cattle; reactions of calves to infestation with the stomach worm; strategic dipping for control of the cattle tick, *Boophilus microplus* (canestrini), in south Queensland; and sperm transport in the fowl.

The *Australian Journal of Applied Science* is, as the name suggests, concerned with the publication of results of original investigations in the broad field of applied science. A recent issue (8, No. 4) contains articles dealing with edge stresses in thin shells of revolution; precision charge comparison for the standardization of X-ray dosimeters; heating of surfaces by buried pipes; heat transfer to liquids boiling inside tubes; an improvement of the vacuum vapour pump with theoretical and practical consequences; laboratory pressure-leaching techniques; slagging of refractories by brown coal ash; and a study of the infra-red absorption spectra of soils.

Besides these more 'formal' journals, the Organization issues a number of other publications dealing with applied researches into particular materials or topics. The Food Preservation and Transport Division, for example, publishes a quarterly journal in which the results of practical investigations of immediate topical interest are set out. The use of various plastic materials for pre-packaging fresh fruit and vegetables, for example, was investigated in 1957, and firm recommendations were made which would be of value not only to those in the trade but also to housewives. Other topics investigated by the Division in recent years include the internal corrosion of food cans; anthocyanin pigments in foods; glass-like deposits in canned foods; the quality of dried-egg products ; the handling and care of fresh unfrozen fish ; discoloration of canned pears ; and the estimation of dissolved tin and iron in canned foods.

The Coal Research Section also produces its own journal containing articles of direct value to those particularly concerned with the large-scale use of coal or its products. Besides articles describing the mineral matter in Australian coals and how coke is formed, the May 1958 issue contains the report of a symposium called to consider how iron castings in foundries could be improved through the use of improved qualities of foundry coke. Articles in other issues of the same journal describe the sulphur minerals in various Australian coals, the methods of cleaning coal and the industrial possibilities of Australian coal tars.

That the Organization is genuinely concerned to see that the results of its many researches are widely disseminated as quickly as possible is shown by two other publications. The Forest Products Division publishes a monthly news-letter which is available to all members of the timber trade and timber users. Topics discussed in some of the latest letters include "How Strong are Wooden Fence Posts ?", the right Australian timbers to use for making clothes pegs, water-borne preservatives for fence posts, and low-pitch roof trusses.

The Agricultural Research Liaison Section produces a most attractive periodical called *Rural Research in C.S.I.R.O.*, which provides a summary of recent research and explains its practical significance. Among subjects which have been dealt with over the past year are the following : Kimberley horse disease ; inbreeding merinos ; tolerance of sheep to salt ; plant nematodes ; renovating *Phalaris* pastures ; preserving fence posts ; making clouds rain ; crops and pastures for northern Australia ; time losses in haymaking ; scrapie in imported sheep ; rabbit control in New Zealand ; durable pleats in wool ; damage of rice by ducks ; the sheep blowfly ; roundworms of cattle ; 'snorter' dwarfism ; changes in pasture soils ; soil salinity ; the portable soil-moisture meter and the spear grass problem.

Under the able chairmanship of Sir Ian Clunies Ross, assisted by the deputy chairman, Dr. F. W. G. White, and the vigorous executive direction of Dr. S. H. Bastow, the Commonwealth Scientific and Industrial Research Organization has already gathered sufficient momentum to ensure its ever-increasing usefulness in solving the many physical and biological problems which confront Commonwealth countries in the southern hemisphere.

Dr. N. S. Noble, general editor, is to be congratulated on the standard and style of the Organization's publications.

PULP AND PAPER RESEARCH INSTITUTE OF CANADA

NEW LABORATORIES

THE new laboratories of the Pulp and Paper Research Institute of Canada at Pointe Claire, Quebec, were officially opened on September 18 by the Hon. William Hamilton as representative of the Government of Canada. Other speakers included Dr. Lincoln R. Thiesmeyer, president of the Pulp and Paper Research Institute of Canada ; Dr. David L. Thomson, dean of the Faculty of Graduate Studies and Research of McGill University ; and Mr. Fred L. Allen, executive vice-president of the Canadian International Paper Company and chairman of the Institute's board of directors.

Few people employed in the pulp and paper industry of the world, be it in mill management or research, can fail to become aware at a very early stage of their career of the importance of both the fundamental and the applied research carried out at the Pulp and Paper Research Institute of Canada, the research institution jointly sponsored by the Canadian Government, the pulp and paper industry of Canada as represented by the Canadian Pulp and Paper Association, and the Royal Institution for the Advancement of Learning of Canada.

The Institute started as a branch of the Forest Products Laboratories of Canada in 1913, and in its early years was housed in part of two old buildings at the corner of the McGill campus. In 1920 the Canadian Pulp and Paper Association joined its own research activities with those of McGill and the Government and soon the rate and scope of the research activities made larger buildings necessary ; these were built on the same site and opened in 1929. In 1940 the work was consolidated by putting the programme under the supervision of a general director, overall guidance on policy being provided by a joint administrative committee. Finally, in 1950, it was decided to expand the programme still further, and the Institute acquired its present form as a non-profit-making educational and research corporation under Federal charter with a board of directors and a full-time management. To stabilize the financial backing needed for the large-scale research programme, most of the companies in the industry entered into renewable five-year contracts with the Institute in 1953, providing annual support proportionate to their tonnage of production. At the same time the need for greatly enlarged headquarters became urgent ; by 1955 plans for the new laboratories at Pointe Claire, near Montreal, had been drawn up, and the Government agreed to build and equip the new building to the Institute's specifications, the industry contributing part of the equipment. For the time being, the building on the McGill campus will continue to be used for postgraduate studies, some fundamental bench-type research, the main library, etc., but it is hoped that in due course these activities can be transferred to the new site, as funds and space become available.

The Institute has a full-time staff of 168, 131 of whom are technical and scientific personnel. Twenty-two graduates are at present participating in the thesis programme. The operating budget for 1958–59 is 1,500,000 dollars, one million dollars coming from Maintaining Member Company contributions, 100,000 dollars from a continuing annual grant of the Canadian Pulp and Paper Association and the remainder as revenues from sponsored research contract projects, chemical and physical testing and consulting services.

The research programme of the Institute covers a vast field, including the study of the chemical structure and properties of cellulose and polysaccharides, physico-chemical and chemical engineering investigations, for example, physico-chemical studies of paper-making fibres and flow and aggregating properties of suspensions, pulping and bleaching studies, disposal of waste liquor, paper formation, instrumentation and pulp and paper testing, analytical methods and the application of photography and microscopy in research. Thus, the Institute acts as a centre for fundamental research, supplementing the research organizations of individual companies. It stimulates and assists in the postgraduate training of students of McGill University, who are working for higher degrees in science and engineering, especially students whose theses deal with subjects of interest to the industry. Two hundred and fifty Ph.D. students have participated in this programme over the years, including a large number of students of chemistry and some chemical and mechanical engineers; it is hoped that in future students of physics, biophysics and biochemistry and biology will increasingly participate.

The Institute also conducts research at the request of individual companies, groups of companies and other sponsors in allied industries.

At the same time, the Institute acts as a clearing house and distribution centre for technical and scientific information, which is published in the form of monographs, bibliographies, translations, and critical reviews. Work carried out at the Institute is published in technical reports and articles in the periodical literature.

The different aspects of the work being done at the Institute were fully taken into account when planning the new building. Two-story blocks house the department of physics, physical measurement and electron microscopy; the mechanical engineering development sections with the adjacent chemical pulping pilot plant; the department for woodlands research, chemical pulping and fibre research, photography and microscopy and chemical analytical services, etc.; there are a refiner and stock-preparation building and a bleaching and small-scale pulping laboratory together with all the ancillary services such as woodworking, sheet metal and pipe-fitting shops, engineering offices, control laboratories, administrative offices with the branch library and a printing and duplicating shop. The buildings were designed to permit unrestricted expansion of any major section without interference with any other, this requirement being met by arranging the building in four wings each of which houses a particular type of operation. The design also permits working space to be redistributed both horizontally and vertically.

To work in buildings specially designed for the purpose will greatly assist the staff of the Institute in carrying out their investigations, and all workers in the industry can thus look forward to receiving an ever-increasing flow of valuable data and information.

S. LAMMLE

SCIENCE AND CIVILIZATION

IN his Sir Henry Simpson Newland Oration before the Australian Medical Congress at Hobart on March 5, now published in the *Australian Journal of Science* (20, 251; 1958), the Prime Minister of Australia, the Right Hon. R. G. Menzies, dealing with "Modern Science and Civilization", examined the place of science, including military science, in modern society. Great talent in science is not the monopoly of any one country, and Mr. Menzies, agreeing that the U.S.S.R. is training a greater proportion of its population in applied science than is any other country, pointed out that the Soviet Union could conscript young men and women into science at will and that there was reason to believe that Soviet technological man-power was excessively concentrated upon military production. The Soviet achievement with artificial Earth satellites should therefore be regarded with a sense of balance and not as a tragedy. Even if some ultimate military purpose lies behind the recent exercises, it simply means that the statesmen of the free world must seek both to maintain such a power of destruction in war as would deter aggression and also continue their efforts to persuade the Communist Powers that the immense possibilities of applied science should be increasingly diverted to the service of the peaceful needs of men and women.

A main theme of Mr. Menzies's address was to emphasize the need for a balanced judgment and to show how easily our own standards of civilization could be distorted. Scientists, he remarked, are not a race apart. They are citizens, bound to a social consciousness and social duties, and cannot, any more than non-scientists, stand apart from the great moral issues. The liberty of the scientist to pursue his chosen study is part of that great structure of self-governing and self-disciplined freedom which the institutions of the democratic world had painfully but persistently developed. That liberty is under challenge, and the scientist has a special interest and responsibility to share in its defence. Natural philosophy cannot make its best contribution to life unless accompanied by a moral and mental philosophy to give it balance. It would be calamitous for the specialist to contract out of the formulation and expression of a social consciousness which recognizes the paramount need to preserve the spirit and institutions of freedom.

After referring to some of the achievements in research of the free peoples, besides which those of the Communist world are insignificant, Mr. Menzies insisted on the need to take long views if civilization is to advance. It is a short answer to the Soviet achievements in the *Sputnik* field to suggest that we need only produce more and better scientists. The crucial question is for what purpose such scientists are to be used. We must recognize the danger of adopting Soviet methods to achieve Soviet results. Provision for scientific defence is for us solely a means of preserving democratic freedom and civilized individual rights. If such provision came to be regarded not as a free national effort but as something requiring the abandonment of freedom and acceptance of authoritarian control, we would have abandoned the case against Communism in the very effort to maintain that case.

Pointing out further that without more scientists and more scientific research the material future of the free world could not be assured and enlarged, Mr. Menzies also referred to the danger here of confusing ends with means. Whether scientific advance means human salvation or a new and complicated form of technological slavery depends on our character, our broad intelligence and our wise and understanding judgment. We must be ready to meet aggression with purpose as well as vigour, but our social policies and particularly our educational policies must be so devised as to encourage sanity and responsibility, and discover blundering accident. Psychologically, the true answer to the threat of war must be found in the improvement of the nature of man himself. The true end to be served is the enlargement of the human mind and spirit. We need more scientists, but also more scholars; more scholarly scientists; more scientific scholars; more historians and philosophers and poets. If science is truly to serve the cause of civilization it will be because the people who use the advances of science have grown to use them in a civilized way. Not all the most brilliant successes in laboratories and factories and fields would make a nation great in the eye of history if it had failed to enthrone the human spirit and to set about it knowledge, and justice, and patience, and understanding.

RADIO RESEARCH, 1957

While research work devoted to various aspects of radio wave propagation is vital and should continue, it is recommended by the chairman of the Radio Research Board in his annual report[*] that the research programme of the Department of Scientific and Industrial Research Radio Research Station at Slough during the next five years should be broadened in scope, to ensure that experience is gained and progress made with other important topics. So far as possible, new fields of research should bear directly on practical applications, and examples include molecular amplifiers and oscillators, and the design and properties of microwave aerials. The radio transmissions from artificial Earth satellites, orbiting so that the source is sometimes within and sometimes above the ionosphere, already have provided a valuable new tool for examining ionospheric propagation, and frequency and directional measurements on the first two U.S.S.R. satellites were made at Slough. More accurate position data for the satellites are awaited before a full analysis of the results obtained is possible.

The work of the Radio Research Station is described in detail in the report of the Director, special emphasis having been given to items directly connected with the International Geophysical Year. In addition to the ionospheric observatories at Inverness, Port Stanley (Falkland Islands), Singapore and Slough, equipment designed or built at the Radio Research Station has been in operation at Halley Bay (Antarctica), Ibadan (Nigeria) and Port Lockroy (Grahamland). The Station has also been designated one of the four World Data Centres for the collection of all International Geophysical Year ionospheric data, the others being at Boulder (Colorado), Moscow and Tokyo. Data from about one hundred stations are sent directly to Slough, while those from some two hundred other stations arrive through the other three Centres.

Routine measurements over the current sunspot maximum period have yielded the highest monthly mean values of $F2$ critical frequency ever recorded over twenty-six years. This experience suggests that in considering the allocation of appropriate frequencies for short-distance radio communication, a frequency of 60 Mc./s. may be taken as the upper limit ever likely to be used in normal F-region propagation. Work has continued on the selection of a suitable ionospheric index of solar activity, primarily as an aid to forecasting propagation conditions. A preliminary investigation suggests that it might be possible to produce a permanent set of charts which would give the critical frequency at any point in the world for any phase of the sunspot cycle (defined in terms of the ionospheric index of solar activity), and which ultimately should render many of the current routine ionospheric measurements unnecessary.

Work on oblique-incidence radio propagation in the high-frequency and very high-frequency bands has continued. An investigation is being made into a possibility that commercial use may be made of the observed lateral deviations of the propagation direction from the great circle path for frequencies of the order of 20 Mc./s. when the latter mode has faded out. This phenomenon is not fully understood, but is thought to be due to some form of ground scattering. The value of the plan-position-indicator 'back-scatter' technique in the investigation of propagation modes to long distances is now established, and experiments are being made to compare the field-strength for forward propagation on a frequency of 17 Mc./s. with that for scatter reception from the same range. Another field of investigation is the forward-scattering of very high-frequency signals in the E-region, and associated with this form of propagation are the strong momentary enhancements of signal which are attributed to reflexions from sporadic meteors.

Long-distance 'scatter links' for ultra high frequencies, by which communication is obtained through forward scatter in the troposphere, are also being investigated at the Radio Research Station. Experiments are in progress on frequencies of 53, 1,370 and 3,500 Mc./s. used over different path-lengths, with the view of clarifying the problem of whether the propagation is maintained as a result of random fluctuations of refractive index caused by turbulence throughout the whole troposphere, or is due to variations of refractive index in relatively restricted layers of the troposphere. As an aid to this study, direct measurements of tropospheric refractive index have been initiated and have so far yielded encouraging results. Work has continued on the measurement of atmospheric radio noise, and equipment has been developed for routine use during the International Geophysical Year for measuring the detailed features of the noise in the frequency-range 15 kc./s.–30 Mc./s. with the view of elucidating the mechanism whereby individual lightning flashes give rise to noise at different frequencies.

[*] Department of Scientific and Industrial Research, Radio Research 1957: The Report of the Radio Research Board and the Report of the Director of Radio Research. Pp. iv+43+4 plates. (London: H.M. Stationery Office.) 3*s*. 6*d*. net.

Observations of the phase and amplitude characteristics of very low-frequency waves (10–20 kc./s.) reflected from the ionosphere are also described in "Radio Research 1957". The experimental work, which bears directly on the application of such waves for navigational aids over long distances, is being supplemented by theoretical work on the propagation of very low-frequency waves.

In addition to the work on radio propagation over a wide frequency-range, the Department is engaged on the development of radio-frequency power measuring standards, and research into semi-conductors and magnetic and dielectric materials. Work on germanium has been superseded by that on silicon filaments and commercial transistors, with particular reference to performance at very high radio-frequencies. The magnetic properties of a wide range of ferrites and other metal oxides and their applications to microwave measurements are being investigated.

Some of the work described in the report is undertaken, under contract with the Department, at various universities. A list of papers published during 1957 is given as an appendix. GEOFFREY M. BROWN

ECOLOGY OF SOIL FUNGI

THE growth, activities and interrelationships of fungi in soil provided the basis for a symposium on "The Ecology of Soil Fungi" held at the University of Liverpool during August 19–21. The meeting, attended by ninety scientists from thirteen countries, was divided into six sessions, which were presided over, respectively, by Prof. N. A. Burges (University of Liverpool), Dr. P. W. Brian (Imperial Chemical Industries, Welwyn), Dr. J. Harley (University of Oxford), Prof. J. Guillemat (École National d'Agronomique, Grignon), Prof. J. Ziemiecka (Institut Uprawy, Pulawy, Poland) and Dr. H. Katznelson (Canadian Department of Agriculture, Ottawa). Each session included a review of one aspect of the subject and four or five shorter papers: most of the twenty-eight papers presented were circulated before the symposium and this undoubtedly contributed greatly to the very lively discussions.

Review papers by Dr. J. H. Warcup (Waite Agricultural Institute, Adelaide, read by Dr. Parkinson and J. S. Waid (Fisons, Levington) dealt, respectively, with the isolation and estimation of activity of fungi in soil and the effect of environmental conditions on fungal growth in soil. Synecological investigations which were afterwards discussed included: the fungi associated with pine litter and couch grass debris (Dr. D. Parkinson and B. Kendrick, University of Liverpool); the distribution of Chytrids in lake muds and soil (Dr. L. G. Willoughby, Fresh Water Biological Association, Ambleside); the microflora of sandy soils in the Sahara (Dr. J. Nicot, Natural History Museum, Paris); the fungal flora of tidal mud flats before and during colonization by *Salicornia stricta* (Dr. G. J. F. Pugh, University of Nottingham); the growth of fungi in forest and grassland soils (Dr. R. H. Thornton, Soil Bureau, Wellington, New Zealand, read by Dr. Parkinson); and the rhizosphere flora of *Abies* of different ages (Dr. R. Moreau, École Nationale de Médecine et de Pharmacie, Besançon). During the course of these papers and the discussions, the need for a greater knowledge of the origin of fungal isolates was emphasized. The use of the soil dilution plate count method, a subject of some considerable debate, was ably defended by Prof. J. Montegut (École National de Horticulture, Versailles), and an account of the use of this method in studies of the effects of nitrogen, phosphorus and potassium on soil fungi was submitted by Profs. J. Guillemat and J. Montegut. Dr. E. H. Garrard (Ontario Agricultural College) surveyed the detailed work on *Streptomyces scabies* at Guelph. Direct-observation studies of *Verticillium albo-atrum* in soil and tomato roots were described by Dr. G. W. F. Sewell (East Malling Research Station), and Dr. H. Tribe (University of Cambridge; read by Dr. S. Hepple, National Institute of Agricultural Botany, Cambridge) discussed his observational work on the decomposition of buried cellulose film.

A review by Dr. Brian of the antagonistic and competitive mechanisms limiting survival and activity of fungi in soil was followed by an account of antagonism as the background in which fungi live (Dr. D. Park, University of Manchester), and a description by Dr. R. Barton (University of Manchester) of investigations of substrate colonization by *Pythium mamillatum* under different conditions. Drs. A. G. Winter, F. Schonbeck and H. Peuss (Botanische Abteilung Madans, Köln Merhiem) discussed biotic factors, with reference to 'hyphospheres' and mycorrhizæ, affecting the development of soil fungi. Soil fungistasis, which Dr. Brian also included in his survey, was the subject of a paper by Dr. C. G. Dobbs, who reviewed some methods of study developed at the University College of North Wales, Bangor. Drs. Dobbs and J. Bywater (Bangor) described a seasonal variation in fungistasis in certain soils, and Dr. R. M. Jackson (Rothamsted Experimental Station) discussed the effect of living roots on the germination of fungal spores in soil.

Prof. Burges, in his paper "Dynamic Equilibrium of Soil Populations", discussed the effects on the soil micropopulation of seasonal fluctuation in depositions of organic matter. The uses of radiocarbon in studies on cellulose and lignin breakdown were described by Dr. J. Mayandon and Prof. P. Simonart (University of Louvain), while problems associated with the isolation of humic acid and its utilization as a nutrient by fungi were the subjects of a paper by Prof. Burges and Miss P. M. Latter. Certain aspects of fungal physiology in relation to soil studies were reviewed by Dr. Harley, whose paper was followed by accounts of the use of physiological methods, relating to oxidative metabolism, in mycological studies (Dr. D. Boulter and H. M. Hurst, University of Liverpool) and a demonstration by Dr. M. E. K. Henderson (Macaulay Institute, Aberdeen) that a number of fungi are able to decompose molecules related to lignin. Prof. C. G. C. Chesters (University of Nottingham) reviewed problems associated with the decomposition of organic matter in soils and stressed that all the different organisms concerned should be considered.

Dr. Katznelson, in an evening lecture, surveyed the work of the Bacteriology Division of the Canadian Department of Agriculture on rhizosphere problems. The ecological events in the rhizosphere and the general health of the plant were discussed in the light of the results of these studies.

Demonstrations, which were available for inspection throughout the period of the symposium, included an exhibition of the use of tracer techniques with special reference to studies of fungal growth in soil (Dr. E. Grossbard, Grassland Research Station, Hurley), the screened immersion plate technique (Dr. Thornton), and examples of soil sections prepared by a resin impregnation method (Dr. S. Hepple and Prof. Burges). The other exhibits were concerned with mycorrhizal studies. Slides and figures illustrating internal and external mycelial phases of vesicular-arbuscular endophytes associated with grass roots were presented by Dr. T. H. Nicolson (University of Nottingham), and Dr. B. Mosse (East Malling Research Station) demonstrated a method of obtaining pure inocula of an *Endogone* sp. capable of causing vesicular-arbuscular mycorrhizal infections: typical infections produced in apple, strawberry and onion roots were shown. Dr. D. G. Downie (University of Aberdeen) demonstrated strains of *Rhizoctonia solani*, pathogenic to potato, wheat and cauliflower, which stimulated embryo development of *Orchis purpurella*, and Dr. I. Levisohn (Bedford College, London) showed the growth of mycorrhizal mycelia on sterilized litter.

It is a pleasure to record the generous hospitality of the University of Liverpool and the excellent organization of this most informative and enjoyable meeting. The organizers are preparing the full proceedings of the symposium for publication by the University of Liverpool Press.

PHYSICS OF ICE MOVEMENT

A SYMPOSIUM on the "Physics of Ice Movement" was held at Chamonix during September 16–24. It was organized by the International Association of Scientific Hydrology for its daughter Commission for Snow and Ice, and was attended by some eighty-five glaciologists from fifteen countries. The work of the symposium was greatly facilitated by the feat of the secretary of the Association, Prof. L. J. Tison, in publishing the forty-one papers submitted for the symposium in time for the opening session*. The president of the Commission, Prof. R. Finsterwalder (Munich), presided over the symposium, and Prof. A. Bauer, one of the vice-presidents, organized the details; despite poor weather, he managed to arrange two whole-day excursions of great glaciological interest as well as twelve working sessions. It is, of course, impossible to summarize all the papers here, and I will only try to give some impression of the material presented in the wide range of relevant subjects discussed, which ranged from the deformation of single crystals of ice to the behaviour of the Antarctic ice sheet.

Prof. U. Nakaya (Sapporo, Japan) reported the results of some very beautiful tests performed on single crystals of ice of great perfection derived from an Alaskan glacier. Rectangular bars cut from these crystals in various orientations had been deformed by bending, and the resulting deformation studied by shadow photography, which reveals the glide planes, and by polarized light, to determine changes in crystal orientation. All the phenomena of gliding and low-angle boundaries observed in hexagonal metals are to be seen, and the geometry of the deformation, deduced by Nakaya, was shown by Dr. J. F. Nye (Bristol) in the symposium to have a close relation to the theory of deformation by continuous distributions of dislocations. The flow law for ice single crystals was discussed by Dr. T. R. Butkovich and Dr. J. K. Landauer (Snow, Ice and Permafrost Research Establishment, United States), who found that for single crystals, like polycrystalline aggregates, the relation between minimum strain-rate and stress can be well represented by a power law for stresses around 1 bar. They used shear tests, and found that if the crystal is oriented for easy glide on the basal plane, the flow is considerably faster than for polycrystals, whereas if the specimen is oriented so that no glide on the basal plane is possible under the applied stress, then the minimum strain-rate is of the same magnitude as that of polycrystals. Butkovich and Landauer also reported results of tests on polycrystalline ice, and further tests of this kind were reported by Prof. S. S. Vyalov (U.S.S.R.) and by Dr. S. Steinemann (Neuchâtel, Switzerland). They all confirmed that a power law represents the data well over a range of strain-rates from 10^{-9} to 10^{-5} sec.$^{-1}$, but at the limits of this range there are signs that the law ceases to hold, in the sense that the power decreases for the low strain-rates and increases for the high ones. Steinemann also found that he could plot a similar power law for the final strain-rate to which the specimen settles down (as opposed to the minimum rate). In this state the ice is recrystallizing during the creep, and it is of particular interest that he has results for both compression and shear tests so that the relations usually assumed to hold between the results of these two types of stressing system can be tested. He finds that the relations are not obeyed, and that the disagreement is particularly bad in the case of the final rate—a result which is perhaps not so surprising when it is realized that the recrystallization is producing quite different textures in the two cases. Since, however, it is this final rate which is probably most relevant to the rate of flow observed in glaciers, this may well mean that glacier theories made with the usual assumptions are subject to some error. Dr. J. W. Glen (Birmingham) in his paper discussed what possibilities there might be for a flow law without making the assumptions in question.

Experiments on glaciers which have bearing on the mechanical properties of ice were reported by several authors. Dr. B. L. Hansen and Dr. Landauer (Snow,

* Union Géodésique et Géophysique Internationale, Association Internationale d'Hydrologie Scientifique, Symposium de Chamonix 16–24 Sept., 1958. (Gentbrugge: Association Internationale d'Hydrologie Scientifique (61 rue des Ronces), 1958.) Pp. 394. 300 frs. belges.

Ice and Permafrost Research Establishment) used measurements of the rate of closure of a hole drilled 1,346 ft. into the Greenland ice sheet to deduce the flow law of the ice, and found results in good agreement with the laboratory work, and Dr. C. C. Langway of the same laboratory reported measurements on the pressure of bubbles in the cores removed from this drill hole which showed that the bubble pressures largely reflected the weight of the overlying ice. However, if the specimens were kept for one year before testing, the bubble pressure never exceeded a certain value, showing that bubbles of greater pressure than that, although they had survived intact the process of being brought to the surface in a core, had relaxed their pressure during the year, and microscopic examination showed small cracks spreading from these bubbles. A further series of mechanical tests on ice were reported by Prof. Nakaya, who has measured the resonant frequency and the damping of bars of ice from various sources as a function of temperature. Recent results which he reported in the symposium, but which are not in his submitted paper, show that the peaks in a plot of damping versus temperature depend critically on the ice used, peaks being present in glacier ice which are not present in single crystals, and laboratory ice being different again. Nakaya's interpretation of this in terms of such things as the mechanical properties of grain boundaries was challenged by Steinemann in the symposium, who suggested that perhaps proton movements associated with the boundaries might be responsible—thus emphasizing that ice, though in many ways similar to a metal, has its differences.

Steinemann also discussed the recrystallization structures of ice, as did Prof. P. A. Shumskiy (Moscow) and Dr. G. P. Rigsby (San Diego). Steinemann used the results of his laboratory tests to discuss the recrystallization and intragranular movements that occur in glaciers, Shumskiy distinguished six mechanisms of straining and their corresponding structures according to the magnitude and type of stressing, and Rigsby presented the results of observations of the preferred orientations found in glaciers and after laboratory tests. In a second paper, Steinemann discussed the applicability of laboratory tests made on ice at temperatures below the melting point to the discussion of the behaviour of temperate glaciers, which are at their melting point and therefore contain some liquid water. He has analysed the stability of the liquid phase theoretically, and concludes that water droplets will only be stable at the intersection between four grains. Thus, until a certain quite high percentage of the ice has melted, the temperate glacier will consist of essentially 'dry' ice with water droplets at four-grain intersections. These droplets will raise the effective stress on the rest of the ice somewhat, but not by a factor out of proportion to the fraction melted. As a result, Steinemann concludes that results of tests on cold ice can be applied to temperate glaciers without serious error.

Naturally, several of the papers were devoted to aspects of the theory of glacier flow. One of the main topics discussed here was the propagation of surges through glaciers. If a glacier develops a greater thickness in some part, as a result, for example, of a very snowy winter, a wave of increased thickness will travel down the glacier at a velocity greater than the velocity of flow itself. A paper on the theory of this phenomenon was published earlier this year in *Nature*[1], and at the symposium, Prof. L. Lliboutry (Grenoble) analysed the observations made on the Mer de Glace during 1891–95 by Joseph Vallot to test this theory. He showed that, although there was qualitative agreement in that a wave of increased thickness moved through the glacier several times faster than the flow velocity, the agreement was not quantitative, and he suggested various possibilities to account for this. His main suggestion was that the friction on the bed may not be completely accounted for on the current theories, but that at high speeds it may diminish considerably due to the inability of the ice to close up behind obstacles past which it has flowed. Dr. J. Weertman (Washington, D.C.) also presented a paper on the subject of surges in which he developed further the theory of their propagation, and in particular discussed the question of the change in shape of the surface of such a surge.

Another sort of wave on a glacier was discussed by Dr. Nye; the waves in question are the undulations which form beneath ice falls and which have a wave-length corresponding approximately to the flow in one year; they are often called wave ogives, and sometimes pressure arches, since pressure was assumed to be responsible for their formation. Dr. Nye has pointed out that in an ice fall where a high velocity is reached, accompanied by an extension of the ice, such waves are to be expected from the fact that glacier flow continues throughout the year, whereas the ablation (loss of ice from the glacier surface) occurs only in summer. Using a simple theory in which it is assumed that the velocity is constant throughout the year and that the ablation occurs suddenly once a year, he showed how such waves could be predicted from velocity and ablation data. He then applied this theory to the ice fall on Austerdalsbreen (a Norwegian glacier), for which measurements of these quantities are available, and found that the location of the crests and troughs agrees well with the predictions, and the order of their amplitude is right, though they are, in fact, less marked than the theory predicts —a result that is to be expected if the assumptions made in the theory are relaxed in a reasonable way.

Among others who discussed glacier theory, Prof. M. Matchinski (France) emphasized the importance of obtaining glacier theories which could be used to describe any glacier of complex shape, and proposed a theory to do this containing parameters to be determined from the glacier itself, and Prof. D. Tonini (Italy) suggested the use of the concept of the characteristic time of a glacier to describe the rate with which the outflow of material on a glacier responds to a change in its accumulation.

Measurements of ice movement on glaciers were naturally also discussed, and here one of the most interesting contributions came from Prof. R. G. Millecamps and M. M. Lafargue (Paris). They have sunk a large number of barium titanate ultrasonic transmitter/receiver units into the ice at the corners of a rectangular lattice, and have used measurements of the time taken for signals to travel between the different units for determining the strain suffered by the ice. At present, only preliminary results are available, and these seem to be curiously irregular; however, the technique is clearly one that holds out great promise, since it enables the full deformation of the ice through the depth of the glacier to be measured. A second technique of great importance was reported by Profs. R. P. Sharp and S. Epstein (California Institute of Technology). They have used the variations in the ratio of the isotopes oxygen-18 and oxygen-16 to determine the history of different parcels of ice. This ratio varies according to the season of the year, and also the altitude of the place in which the snow fell, and they quoted several examples where it had been of value in confirming whether ice samples found to be close to each other in the lower reaches of a glacier in fact came from the same region.

One of the most interesting developments in more orthodox methods of glacier study is the increasing use of photogrammetry, both terrestrial and aerial, to determine not only the map of a glacier, but also the velocity of flow and the variation in surface height of glaciers. For flow measurements, the photographs are usually taken with an interval of several days, and preferably from an identical position, but it was shown that even aerial photographs (which are necessarily not taken from exactly the same position on two different flights) could be used, if necessary, to determine glacier flow. There was some discussion of the best method of analysing such photographs, M. M. Baussart (Paris) favouring the plotting of two maps, one for each date, and deducing the velocity either from these or from the data from which they are constructed, whereas Dr. W. Hofmann (Munich) preferred to use two photographs taken at different times to give the velocity directly. However, it seems clear that both techniques give accurate results, and can even do so when no ground control at all is available. There were also many reports of measurements of glacier flow and variations of the more conventional kind, and perhaps the most interesting of these were some of the first results of International Geophysical Year expeditions to Antarctica given by Dr. L. D. Dolgushin (Moscow) and Dr. J. H. Zumberge (Ann Arbor, Michigan). The former described the features developed by flow in the large outflow glaciers of Queen Mary Land, while the latter reported on the deformation features on the Ross Ice Shelf.

THE HUMAN OPERATOR AND HIGH-SPEED FLIGHT

THE first International Congress of Aeronautical Sciences was held in Madrid, during September 8–13, when representatives from twenty countries met to discuss forty-five papers delivered under the presidency of Dr. Theodore von Kármán.

The subjects included theoretical and applied science dealing with structures, aerodynamics, speed, height, range, propulsion, the handling of supersonic aircraft, navigation, aircraft taking-off and landing vertically, engine noise, and also the important subject of human engineering.

The human element is the limiting factor which faces the designer and operator of the new generation of high-speed aircraft. But considerable information has been accumulated over the past fifteen years about the physical and mental strains on a pilot subjected to violent manœuvres, and also about the psychological factors causing fatigue and thus an involuntary falling-off in efficiency. This experience has come from branches of science outside the general field of aeronautical engineering, namely, in the aero-medical field including physiology, neurophysiology and psychology.

From the early stages of design study for a new aeroplane the problem of the human operator is studied by scientists working with the design team to ensure that human limitations do not prevent the machine being flown to the best advantage.

Military and civil aircraft present some common problems, but naturally those of the combat aeroplane are particularly difficult; pioneering work on military aircraft is frequently useful for the later generations of civil machines, including the now familiar pressure suits worn by air-crews for the protection of the body against physical damage, and radar devices for navigation.

An invariable problem posed by the human operator and his working space in the cockpit lies in variations in size and shape of body, and arm- and leg-reach, all in some way affecting operating comfort and efficiency and involving, for example, the clearance between apparatus, controls, and the canopy. More intangible problems are those concerned with muscle, nerve and brain, underlying the senses and reactions, and much has yet to be discovered.

Laboratories exist in many countries for practical work as well as for theoretical analyses in the study of human engineering, which applies to any task in which physical and mental co-ordination is required of the operator. Too many tasks in the past have been carried out by the human operator adapting himself to the machine, whether it be aeroplane, machine ~~tool,~~ forging machine, or instrument observation.

The aircraft designer is thus increasingly required to range over a varied scientific field, and to consult other specialists on the human operator aspect. The following topics were discussed at the Congress:

(1) Simplification of the work of the air-crew, both physical and mental.

(2) The study of all aspects of visual observation both inside and outside the cockpit, including the design and arrangement of the instruments. Outside the cockpit the angle of view from a pressurized aircraft is limited, and with increase in performance a television display, reliable under all weather conditions, is desirable.

(3) Location, design and shape of controls, levers, and knobs, for instant recognition by sight or touch, day or night.

(4) Reliable information about what fuel remains at any given time, and what aerodromes are available within the remaining range.

(5) Warning lights that are insistent, but not too violent, for vital emergencies, and illuminated descriptive panels for secondary troubles.

(6) Air conditioning and temperature control.

(7) Methods of escape to safety in case of an emergency; the self-contained detachable cockpit dropping by a parachute, after clearing the air wreck, to a suitable altitude from which the crew can escape on their own parachutes.

(8) Disorientation in flight.

(9) Protection against cosmic radiation during space flight.

(10) The problem of weightlessness in space.

Observing, thinking and making a movement takes time whether it concerns operating an aeroplane, a machine tool or playing the piano, but smooth and apparently effortless action by an operator having a mastery of his task shows a high degree of combined skill.

The hazards and increasing complication of flying have encouraged great efforts to be made to reduce the reaction-time of air-crew, between hearing or seeing some signal and acting on it. One action may have to be followed by a second or a third, all taking time depending on how much mental interpretation is required after observing the dials and lights. A good deal of work can be performed quickly by robot-type apparatus ; but it can carry out only what it has been programmed to do, and cannot readily be adapted to differentiate between courses and evaluate alternative action. Robot apparatus, moreover, frequently occupies much space and is weighty, and it needs skilled attention to keep it serviceable.

Extending the pilot's senses without increase in fatigue is an important factor in getting the best out of an aeroplane. Vision is most important : many miles will have been travelled in the few seconds required to stop observing an instrument a few feet away on the cockpit panel, and to sight and recognize a distant aeroplane.

Quick-acting robot apparatus is best used in relieving the pilot of physical tasks ; for presenting the assorted instrument readings as integrated results ; and for displaying a flat television picture of the view around the aeroplane.

While aircraft design and construction has to conform to accepted standards and official specifications, no such definite direction is possible on the more intangible aspects relating to the human operator and so every new experience reported by air-crews is carefully studied, and may be the starting-point for further aero-medical research.

The many instruments on cockpit panels are arranged in groups or in horizontal and vertical rows so that the readings relating to a particular operational function may be viewed together. This helps in the rapid assimilation of facts from which the pilot mentally assesses the conditions. There remain the possible chance of error in observation, and the time-lag before any action follows : to improve matters, apparatus is being developed which will receive the instrumental readings and give the pilot a combined result from which he can take immediate action.

Thus the process of adapting the aeroplane to the lot continues and reduces the chances of accidents e to so-called 'pilot error'. It has been a convention [illegible] attribute many crashes to "an error in judgment [illegible] the part of the pilot" when, in fact, the cause has en due to confusing or difficult operating conditions, hich become more hazardous when the pilot is tigued and flying conditions are bad.

The experience of the past ten years is now being ed in the design study of new manned aircraft, and sks apparently impossible for the pilot are now ing assigned to apparatus with the pilot as the aster mind. For example, an apparatus designed [illegible] relieve the pilot during combat at high speeds is e Ferranti 'Airpass' system (airborne interception dar and pilot's attack sight system). After several ars development it is now fitted in the English ectric *P.* 1*B* high-speed fighter. 'Airpass' starts [illegible] operate when the fighter is beamed in the direction [illegible] a target, it scans ahead and when the target is cated the radar locks on and a computer finds the best course for the aeroplane. The pilot observes the essential facts in his sights and acts at the right time. He has been relieved of the visual strain and the anxiety of determining the correct course and can concentrate on the proper time to fire.

Progress has been helped greatly by the aero-medical pilots who understand test flying and take part in it, co-operating with other specialist scientists in the design team in the study of the operational requirements of a new aircraft, and how these can best be met. A full-scale cockpit model is tested under varying climatic conditions for maximum operational periods. These tests disclose discomforts due to pressure suits, difficulties in making movements to operate controls and switches, and escape facilities. In adapting the future aircraft to the pilot it must be emphasized that operation at supersonic speeds presents conditions of control quite different from those in sub-sonic flight, while kinetic heating demands a cooling system to prevent excessive rises in temperature.

Present-day control columns and rudder pedals will probably give way to a set of small hand levers on the pilot's desk console, which will also have communication aids and signals, the television picture of the outside view being at eye-level beyond the console, and visible to any other members of the air-crew.

The new self-contained type of control cabin can more readily be accommodated within the best aerodynamic shape, avoiding the usual sharp hump in the top curve of the fuselage due to the cabin windscreen and roof. The windscreen spoils good performance at supersonic speeds, and it should not be permitted in the new aircraft using television display. Operation would be entirely by remote control using television and other instruments, but a retractable periscope would be useful for ground manœuvring.

Other fields of human engineering include the operation of cars and lorries, fast Diesel trains, automatic manufacturing plant, and many others co-ordinated by the Ergonomics Research Society and covering international interests.

It would not be realistic to suppose that manned combat aircraft will become obsolete in the near future, and it may be assumed that air-crew will be needed for many military operations, but their task must be made simpler. Unmanned robot aircraft and missiles have a future. But it is unwise to think that these could replace certain attack and defence duties.

The important development of VTOL aircraft (vertical take-off and landing) and STOL aircraft (short take-off and landing) were discussed at the Congress, and it was emphasized that failure-proof apparatus for autostabilization and landing are essential if these types of aircraft are to be successful.

Human engineering applied to helicopters is concerned with control factors quite different from those of the fixed-wing aircraft, but some basic problems are similar. When controlling a helicopter, the pilot is continually using his hands and feet to maintain stability, and at present it is necessary to keep the ground in view, until a reliable automatic pilot system is available to permit safe flying in all weathers.

The special senses reacting to linear and angular movement often prove misleading to a pilot when he is not engaged in steady straight flight, yet these are two of the three main sources of information about orientation which emphasizes the supreme importance of the eyes. Under some conditions of prolonged manœuvre even the eyes may prove misleading for a time during the manœuvre, or immediately after it has been completed. Facts on the limits of human tolerance in aviation and on the question of reaction-times are being accumulated in the leading national institutions, so that more data are available to designers.

Crew for manned space-flights will have to be selected from test pilots trained to retain normal physiological and psychological functions under severe conditions.

Two problems which are particularly difficult to study on the Earth are those of weightlessness, and the effects of cosmic radiation. Weightlessness, which can be studied for short periods under certain conditions of parabolic flight, causes disturbances of muscular co-ordination and the nervous system, leading to awkward functions of certain reflexes. There may also be long-term effects on respiration and disturbance of the alimentary canal. Generally, there is likely to be a reduction of the input of information to the sensory pathways of the brain, and thus some effect on the mental processes. Recent data from *Explorer* satellites and the *Sputnik* 3 reveal a belt of intense radiation between latitude 30° N. and 30° S., at a height of about 6,000 miles and beyond. This may be a serious barrier to manned rockets in this region, but in the equatorial zone there seems to be relatively little radiation, according to the information at present available, so that it may be possible for future manned rockets to avoid this hazard to some extent.

HYDROMEDUSAE NEW TO THE BRITISH LIST FROM THE FIRTH OF CLYDE

By C. EDWARDS

Marine Station, Millport, Scotland

In the course of work on the plankton of the Firth of Clyde a survey of the Hydromedusae has been made from early 1956 to the present date, because of their value as hydrographic and biological 'indicators'[1,2] of conditions in the area. Further, it is thought that they are a valuable guide to the zoogeographical relationships of the Clyde fauna. Finally, this survey may prove of service in the future in the detection of any long-term changes in the fauna.

The Clyde fauna has proved to be rich in number of species of Hydromedusae, forty-seven species having been found during this work. A full report on them will be published on completion of the survey. As, however, the four undermentioned species, new to the British list, have been found, this preliminary note is of value at the present stage.

Plotocnide borealis Wagner. Twelve specimens have been taken in surface tow-nettings at Millport in April and May 1956 and during February-April 1957. None has been found in 1958. Routine daily surface-water temperatures on the dates of capture ranged from 6·1° to 9·0° C. The earlier occurrence of the species in 1957, compared with 1956, reflected the much milder winter and earlier spring of 1957 compared with the previous year. Its apparent absence in 1958 may have been due to the fact that cold winter conditions were unusually prolonged and were followed by an exceptional period of persistent east winds, which delayed the onset of spring conditions and appeared to disfavour certain forms normally occurring in late winter and early spring.

This species has been considered to be an arctic one of circumpolar distribution[3,4], having been reported from western Greenland, the White, Barents and Chuckchee Seas and the Sea of Okhotsk. However, Beyer[5] recorded its occurrence in the Oslofjord between 1946 and 1953, although he suggested the possibility that it may there be an arctic survivor from some cold period, capable of living at the temperature (about 6° C.) of the deeper layers of the Oslofjord.

The survival of *Plotocnide borealis* in the Clyde area as an arctic relict is extremely unlikely. While its accidental introduction into the area in the hydroid stage is possible, it is considered unnecessary to attribute its presence here to that cause. It is a very small medusa, easily overlooked and nowhere reported as abundant, and its apparently disjunct distribution may be due to limitations of collecting. Its occurrence in the Clyde area over at least two years suggests that conditions here are suited to the species. The medusa faunas of the regions from which *Plotocnide borealis* has been reported include a number of other species the ranges of which extend from arctic to boreal regions, such as *Hybocodon prolifer*, *Rathkea octopunctata*, *Staurophora mertensi*, *Tiaropsis multicirrata* and *Aglantha digitale*, all of which occur in the Clyde area. The presence of northern boreal and boreal-arctic forms in arctic seas is well known. For example, Gurjanova[6] has shown, in the case of amphipods, that many Atlantic northern bor species have penetrated into the deeper parts of t Russian arctic seas because of relatively warm wa in the deeper layers of the Arctic basin. It is sign cant that Jaschnov[4] reports that, in the Barents Se *Plotocnide borealis* occurs in the deep layers. T appearance of many boreal species in the waters western Greenland during recent decades, because climatic change, is well known[7]. The presence deep, cool water in the Firth of Clyde may favour t establishment of any cold-water forms entering t area. It is considered that *Plotocnide borealis* can longer be regarded as a purely arctic species, but true distribution must await further discovery. T hydroid stage is unknown.

Bougainvillia muscoides (M. Sars) [*B. nordgaa* (Browne)]. This medusa has hitherto been report only from fjords on the west coast of Norway betwe Bergen and Molde, a single offshore locality nor east of the Shetlands, and one station over the Wyv Thomson Ridge[8]. In addition, the hydroid has be recorded from the west coasts of Sweden and Norwa In Norway the medusae have usually been found fro August to November, and exceptionally in April a May.

The species occurred at Millport in 1956, twenty-one specimens being found between September 18 and October 11. The fact that various stages were taken, ranging from very young ones to adults, indicated that the hydroid was present in the area. This species exemplifies faunal similarities between the west coasts of Scotland and Norway. It is probably present elsewhere along the Scottish west coast, as is suggested by the record from over the Wyville Thomson Ridge.

Bougainvillia macloviana Lesson. This well-known species is widely distributed and abundant in antarctic and subantarctic waters[10]. It has, however, been repeatedly found since 1895, though in limited numbers, in the southeastern part of the North Sea at Heligoland and off the East Frisian Islands, during April, May and June[11,12]. Its occurrence in the North Sea is attributed to transportation of the hydroid on ships from the antarctic.

One adult medusa was taken in the Firth of Clyde on June 14, 1956, and the introduction of the species into this area is similarly explained as due to transportation from the southern hemisphere. Whaling vessels from the Antarctic frequently lie up in the lochs off the Firth.

Tiaranna rotunda (Quoy and Gaimard). This species is recorded from the Straits of Gibraltar and the region immediately to the east, the northern North Sea, fjords in western Norway, the Skagerrak, Davis Strait, the Irminger Sea (between south-west Iceland and south-east Greenland), and the South Atlantic and Antarctic Oceans[3,10,13]. It is a deep-water species only occasionally ascending towards the surface. Russell, in his account of the British medusae[14], included it on the ground that, although not recorded from the British area, it might occur over deep water off our western and northern coasts.

Twelve specimens have been taken off Great Cumbrae Island, Firth of Clyde, two during October and November 1956 and the remainder between July and December 1957. Three were adult, the others very small. The species was evidently resident in the area. With the exception of one adult specimen taken in an oblique haul from 90 metres depth to the surface, all the others were caught in surface townettings. The presence of a considerable body of fairly deep water (attaining 168 m. or more in depth) in the Clyde area has enabled the species to establish itself here.

Of additional interest is the discovery that the young stages, previously unknown, agree very closely with the description and figures of *Modeeria formosa* Forbes[15], based on a single specimen taken off Mull in the autumn of 1845 and not recorded since. It is highly probable that the two species are identical, but, because of the uncertainty of Forbes's specimen, it is advisable not to disturb the well-established name of the species. Descriptions of the young stages will be published in due course.

NUCLEOTIDE POOL OF BREWERS' YEAST DURING GROWTH AND FERMENTATION

By G. HARRIS, J. W. DAVIES and R. PARSONS

Brewing Industry Research Foundation. Lyttel Hall, Nutfield, Surrey

It is known[1,2] that yeasts contain pools of nucleotides analogous to the reserves of amino-acids[3]. A detailed analysis of the nucleotide pool of bakers' yeast at one stage of growth, made[1] by extracting the organism with cold perchloric acid followed by chromatography of the acid-free extract on 'Dowex'-1 (formate), showed that it contained the mono-, di- and tri-phosphates of adenine, guanine, cytosine and uracil together with various new nucleotides, notably uridine diphosphate glucose (UDPG) and uridine diphosphate acetylglucosamine (UDAAG)[4]. We have now examined the nucleotides present in a brewers' yeast (*Saccharomyces cerevisiae*, National Collection of Yeast Cultures, No. 240) at successive stages of growth and fermentation.

The yeast was grown aerobically for 48 hr. and inoculated into brewers' wort, when it was allowed to grow and ferment without agitation. The methods employed for analysing the cells differed from those used by earlier workers in that extraction was performed in two stages, the first using hot aqueous ethanol for a limited period and the second cold trichloracetic acid. The two extracts from each sample of yeast were individually chromatographed on 'Dowex-1' (chloride), following Pontis and Blumson[5], to give the chromatograms shown in Figs. 1 and 2.

Clearly, the total nucleotides are divided by these means into two main groups. The first contained the compounds previously observed in bakers' yeast together with at least five unidentified nucleotides (1–5), while the second group comprised a large number of new components (7–31, Fig. 2). Full details of the properties of the unidentified materials will be published elsewhere. Figs. 1 and 2 reveal, moreover, remarkable changes in the nucleotide pool as the development of the yeast proceeds. In particular, the nucleotides extracted by trichloracetic acid show a considerable increase both in amount and diversification during the first four hours, that is to say, in that period in which the yeast is preparing to undergo its first division. So far as can be judged from the number of samples examined, this increase

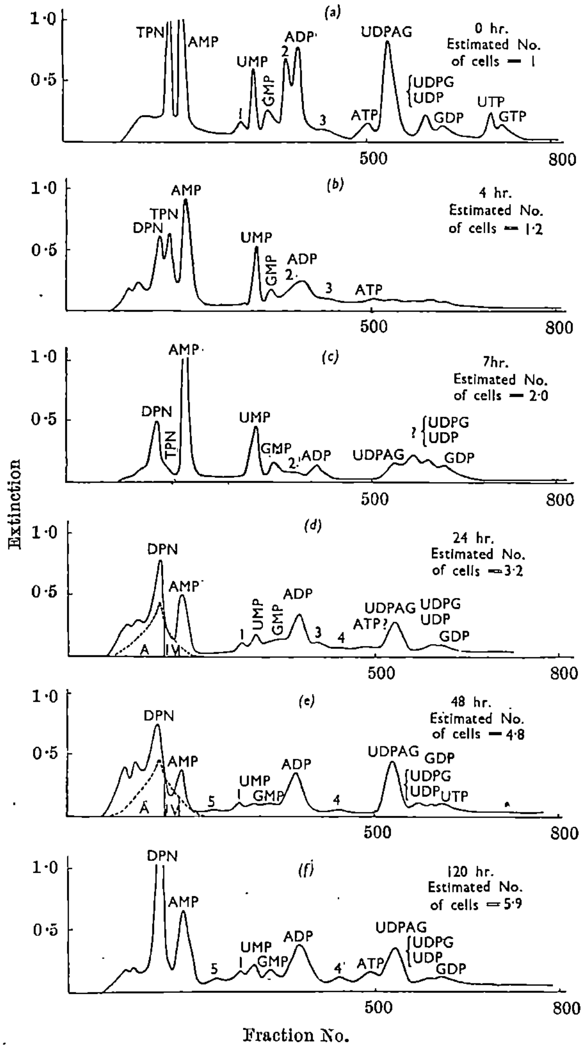

Fig. 1. Key: *A*, adenosine; *G*, guanosine; *U*, uridine; *MP*, *DP*, *TP*, mono-, di-, and tri-phosphate, respectively

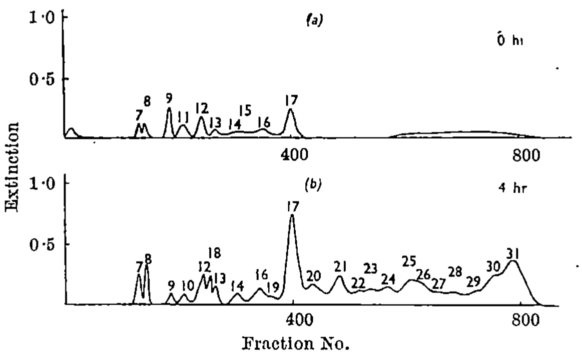

Fig. 2

Figs. 1 and 2. Chromatograms obtained by elution of yeast nucleotides from 'Dowex'-1 (chloride) in a calcium chloride–hydrochloric acid gradient (ref. 5) and determination of the absorption of ultra-violet light in the eluted fractions (each of 10 ml.). Samples of yeast (30 gm.) were removed from the medium after intervals of 0, 4, 7, 24, 48 and 120 hr., and each sample was extracted initially with aqueous ethanol and finally with cold trichloracetic acid. The extracts were chromatographed individually and the substances responsible for the peaks identified tentatively by means of their positions on the chromatogram, behaviour on paper chromatography, and isolation as their calcium salts (ref. 5) and determination of the absorption characteristics for ultra-violet light of the regenerated nucleotides under acid and alkaline conditions

coincides with a fall in the amounts of the nucleotides originally present, a fact which suggests that the nucleotides soluble only in trichloracetic acid are formed at the expense of the compounds soluble in alcohol. That the components soluble in acid appear during the synthesis of nucleic acids further suggests that they are intermediates in this process. In this connexion it is relevant to note that Ogur *et al.*[6] and others[7] have shown, using budding yeast and other organisms under selected conditions, that deoxyribonucleic acid is synthesized before cell division occurs. In addition, the participation of intermediates adsorbed on 'template material' and released only by treatment with acids has been inferred by Miettinen[8] and by Cowie and Bolton[9]. Furthermore, Okazaki and Okazaki[10] demonstrated that certain polymeric deoxyribonucleotides, separable on 'Dowex'-1 (formate), are active growth promoters in the presence of thymidine for a thymidineless strain of *Lactobacillus acidophilus* by virtue of their participation in the synthesis of deoxyribonucleic acid.

The selective extraction of the compounds soluble in acid mentioned above from yeast would appear to offer a means whereby they may be concentrated, separated and investigated structurally. Obviously, their isolation in useful quantity is best attempted at a critical early point in the development of the cell culture as their amounts decline rapidly after active growth sets in, possibly because they undergo rapid turnover during the subsequent life of the culture. In this connexion it would be desirable to study the changes in the nucleotide composition of synchronously budding cells, but adequate techniques for this purpose have still to be devised.

Finally, it has been found in the present work that many of the nucleotides, extracted by either hot or cold ethanol and separated by chromatography on 'Dowex'-1 (chloride), are associated with either peptides or sugars. Indeed, certain peptides at least are chemically bound to the nucleotides as in the case of a number of components located in zone *A* (Fig. 1*d* and *e*). Koningsberger *et al.*[11] have observed the presence of similar nucleotide–peptide complexes in bakers' yeast and, on the basis of the reaction of these substances with hydroxylamine to form hydroxamic acids, have suggested that they are intermediates in protein synthesis. The nucleotides which we have detected also react with hydroxylamine to form hydroxamic acids. While the precise nature of the peptide–nucleotide association remains uncertain (cf. Raacke[12]), it is perhaps significant that the compounds from yeast resemble in respects additional to their reaction with hydroxylamine the amino-acid adenylates containing a phosphoanhydride linkage[13]. For example, as mentioned above, they migrate towards the cathode on electrophoresis and, furthermore, they are eluted from 'Dowex'-1 (chloride) by means of sodium acetate solution at *p*H 5–7 [13]. This latter property makes possible their separation from other nucleotides, particularly tri- and di-phosphopyridine nucleotide (TPN and DPN) and adenosine monophosphate, which cannot be achieved by the procedure of Pontis and Blumson[5]. By employing this improved technique, coupled with chromatography and electrophoresis on paper, concentrates of the nucleotide–peptide compounds have been prepared in purified condition. One such complex, originally occupying section IV of zone *A* (Fig. 1*d* and *e*), unexpectedly proved on purification to have the ultra-violet absorption of the type given by uridine, rather than adenosine, while on hydrolysis it yielded uracil together with a mixture of amino-acids in which arginine, cystine, glutamic acid and leucine predominated. In contrast to the acid-soluble nucleotides discussed above, the nucleotide–peptide compounds are readily obtainable at late stages of the cells' development. Structural investigations both on these compounds and on the above-mentioned intermediates in nucleic acid synthesis are in progress.

PRESENCE OF A FACTOR INHIBITING BITING IN *AEDES AEGYPTI*

By M. M. J. LAVOIPIERRE

Department of Parasitology and Medical Entomology, Liverpool School of Tropical Medicine,
Pembroke Place, Liverpool

EVIDENCE has been obtained[1] that mated and unmated females of the Liverpool strain of *Aedes aegypti* (recently identified by Mattingly of the British Museum as *A. aegypti* var. *queenslandensis*) differ markedly in their avidity for blood. Whereas the mated females show a cyclical biting pattern which appears to correspond closely to the gonadotrophic cycle, the unmated females show no such cyclical biting activity, feed at a high level and lay few eggs. Gillett[2], who has studied ovulation in a Newala strain of *A. aegypti* (in which the unmated females, as in the case of the Liverpool strain, lay few eggs), showed that ovulation occurs a few days after mating; the factor responsible for this behaviour was named the ovulation hormone[3].

In the experiments described in this article at least two factors have been shown to be operative in the gonadotrophic-biting cycle. One of these appears to be identical with that previously described as the ovulation hormone[2,3], while the other is a hitherto unrecognized factor designated here as the 'biting-inhibitory factor'.

As in the earlier studies, the mosquitoes used were *A. aegypti* var. *queenslandensis*, the conditions under which the experiments were conducted being similar to those previously described[1]. Unmated females from a single 'pupal crop' were maintained on sugar water for four days and on the fifth day were offered a blood meal on a human volunteer. All the insects which had taken a full blood meal were then separated off into groups in cages, each group being offered a blood meal again on the sixth and seventh day. On the eighth day of the experiment, when the oocytes had reached the fifth stage, approximately three times the number of recently emerged males were introduced into each cage, mating being observed to occur almost immediately. Half an hour later the males were removed from the cages.

The effect of mating on the biting activity of the females was dramatic. Shortly after the removal of the males the arm of the volunteer was inserted for 10 min. into each cage, at intervals over a period of several hours. In all the experiments the percentage of mosquitoes biting fell steadily with time, and, in most cases, before a period of 2 hr. had elapsed, no mosquitoes would feed (Fig. 1).

In a further series of experiments observations were extended to a period covering several days. It was noted in these studies that the females (offered a blood meal for 15 min.) soon recovered from the biting-inhibitory effect produced as a result of mating, and that by the fourth or fifth hour (occasionally longer in some experiments) biting once more rose to a high level although all the females were fertilized

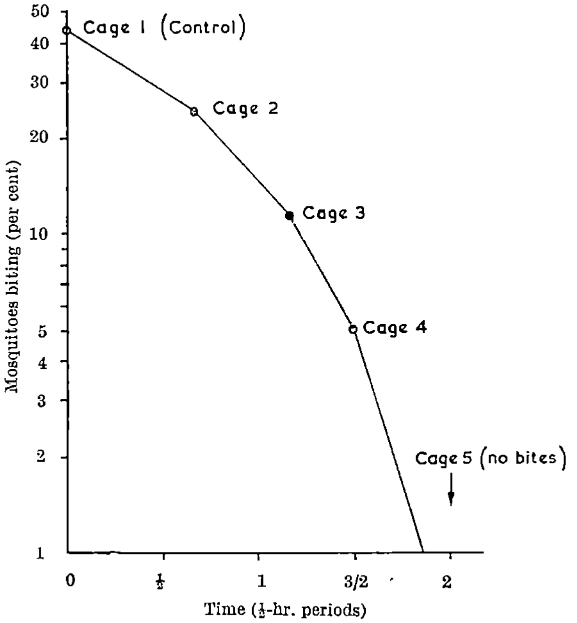

Fig. 1. Graph showing the effect of mating on the biting activity of previously unmated *Aedes aegypti* with fifth-stage oocytes. Each cage contained a group of 50–60 females. Whereas no males had been introduced into cage 1 (the control group), the females in the remaining four cages were mated; all the females were afterwards dissected. The results are plotted on semi-logarithmic co-ordinates

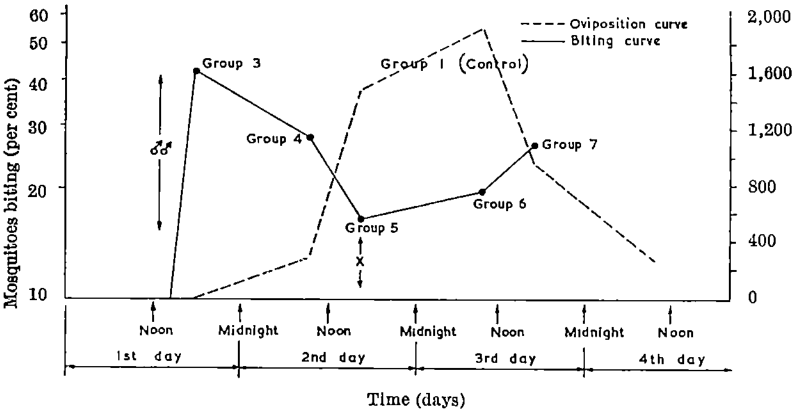

Fig. 2. Graph showing the relationship of the biting curve to the oviposition curve of a population of 520 female *Aedes aegypti* (divided into seven unequal groups) which were mated when the oocytes had reached stage 5. Group 1 (the control; indicated by the broken line) was used for the oviposition curve, while groups 2–7 (joined by the running line) were used for the biting curve, each group being dissected following feeding (group 2 does not appear in the figure because only one bite was registered). The biting curve records only the percentage of females (with fifth-stage oocytes) which fed; not until 5 p.m. on the second day (point *X* on the graph) were the first females found (8 per cent of group 5) which had laid all their eggs. The biting curve is plotted on semi-logarithmic co-ordinates and the oviposition curve on arithmetic co-ordinates

(indicating successful mating), nearly all contained fifth-stage oocytes and no eggs had been laid. As is shown in Fig. 2, the peak of egg-laying activity followed some considerable time after the peak of biting activity.

Although there was some variation in both series of experiments, the same pattern of behaviour was always repeated.

It seems evident from these observations that the biting-inhibitory factor is not the same substance as the ovulation hormone for, if this was the case, ovulation would be expected to follow at, or soon after, the disappearance of the inhibitory effect (4–5 hr. after mating). It therefore appears that in the normal gonadotrophic-biting cycle at least two factors, the production of which is dependent on previous mating, are involved. These two factors operate in harmony in the normal cycle[1], with the result that their individual identity cannot be recognized, but if mating is delayed until the fifth stage of ovarian development it is possible to observe the presence not only of the ovulation hormone[2,3] but also of that of a 'biting-inhibitory factor'.

MAGNETIC PROPERTIES OF SPIN-FREE TRANSITION SERIES COMPLEXES

By Dr. B. N. FIGGIS

William Ramsay and Ralph Forster Laboratories, University College, London, W.C.1

THE magnetic behaviour of the sets of d-electrons which arise for the various transition element ions has received much attention in the literature. It has long been recognized that in the first transition series, where the spin-orbit coupling constants are not large, the magnetic moments which are found are the result of a partial quenching of the orbital angular momentum of the free ion by the ligand fields to which the ion is subject in a co-ordination complex. Frequently, the approximation that the spin-orbit coupling is much less than the thermal energy available for populating excited states is made—that is, $\lambda \ll kT$—so that all the members of the ground-state multiplet are taken to be occupied. (I employ λ, the spin-orbit coupling constant for the free ion spectroscopic term, in order to emphasize the fact that I am dealing with spin-free complexes only.) It may then be expected that the moments involved should lie between $\sqrt{\{4S(S+1)+L(L+1)\}}$ and the spin-only $\sqrt{\{4S(S+1)\}}$, according to the degree to which L, the orbital angular momentum, is quenched[1]. However, since values of λ lie between 50 and 800 cm.$^{-1}$ for the first transition series free ions, and are not much lower in actual complexes[2], and kT at room temperature is about 200 cm.$^{-1}$, it is obvious that such an approximation is unjustified. It is necessary to examine the ground-states of the ions in somewhat more detail in order to obtain a satisfactory account of the moments observed. This has been done in considerable detail for a few cases[3–6] and more generally for some others[7,8]. The purpose of this article is to summarize in a simple and easily utilized form the results available from the literature for the various d^n configurations and to complete the calculations for configurations not so available.

The ligand field to which a transition-element ion is subject in a complex may be classified, for the present purposes, as (1) strong if it is sufficiently large to force the pairing of electron spins; (2) medium if it is large enough to force the electrons to occupy 'private' d_ε and d_γ orbitals, provided they do not have to pair off spins to do so; and (3) weak if the spectroscopic terms of the free ion are maintained, although split into a number of components. A medium ligand field corresponds to the breaking down of the 1–1 coupling part of the Russell-Saunders coupling scheme for the free ion, a strong field to the breaking down of the s–s coupling part as well. For a great many co-ordination compounds the approximation that the ligand field is of entirely cubic symmetry is not unreasonable if it is desired to deal with the average magnetic properties of ions only, as distinct from the magnetic anisotropy. In this article the magnetic properties of all the d^n configurations will be outlined under this assumption for both medium and weak fields. The problem of strong fields under this assumption has been dealt with[7]. In refs. 3 and 4 the magnetic anisotropy was of importance, and here we simplify the results to cubic symmetry. In ref. 8 the expressions for d^6 and d^7 in medium cubic fields are given; we make the simple extension to d^2, d^3, d^4 and d^8. Finally, the results of calculations on the weak field configurations of d^2, d^3, d^7 and d^8 are presented. Most of the information is presented in graphical as well as analytical form to facilitate the appreciation of its significance and its application to the interpretation of the behaviour of magnetic moment with temperature.

Griffith[8] has shown how the matrix elements of spin-orbit coupling and the magnetic moment operator may be obtained for all the medium field configurations $(d_\varepsilon^n d_\gamma^m)$ by analogy with p^n configurations by means of arguments based on group theory. Alternatively, they may be obtained by direct calculation after the manner of Kotani[7], and the results set out in Figs. 1–4 were so obtained. For the D spectroscopic terms which arise for transition element ions there is no difference between the weak field and the medium field approximations. Penney and Schlapp[3] gave matrices for ligand fields of low symmetry for the F terms, which were not susceptible to exact solution in the general case. With the approximation of cubic symmetry, exact solution is possible, and this forms the basis for the weak field results for F terms quoted here.

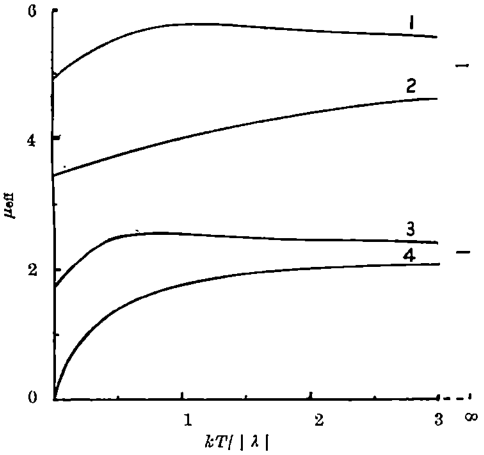

Fig. 1. μ_{eff} versus $kT/|\lambda|$ for ^2D: Ti^{3+} (octahedral, λ positive) and Cu^{2+} (tetrahedral, λ negative),

$$\mu_{\text{eff}}^2 = \frac{8 + (3x - 8)\exp(-3x/2)}{x\{2 + \exp(-3x/2)\}} \text{ with } x = \lambda/kT$$

^5D: Mn^{3+} (tetrahedral, λ positive) and Fe^{2+} (octahedral, λ negative)

$$\mu_{\text{eff}}^2 = \frac{3\{28x + 9{\cdot}333 + (22{\cdot}5x + 4{\cdot}167)\exp(-3x) + (24{\cdot}5x - 13{\cdot}5)\exp(-5x)\}}{x\{7 + 5\exp(-3x) + 3\exp(-5x)\}}$$

(1) ^5D, T_1; $d_\varepsilon^4 d_\gamma^2$, λ negative. (2) ^5D, T_1; $d_\gamma^2 d_\varepsilon^2$, λ positive. (3) ^2D, T_1; $d_\gamma^4 d_\varepsilon^5$, λ negative. (4) ^2D, T_1; d_ε^1, λ positive

There is no difference between weak and medium field cases

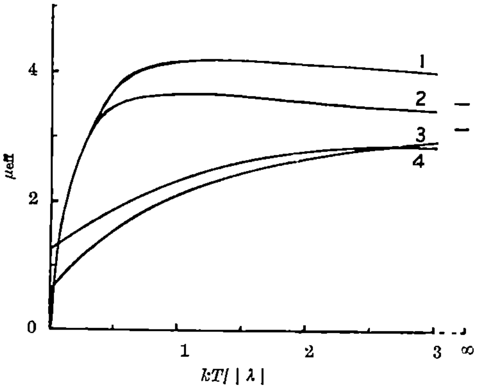

Fig. 2. μ_{eff} versus $kT/|\lambda|$ for V^{3+} (octahedral, λ positive) and Ni^{2+} (tetrahedral, λ negative). (a) weak field (^3F) and (b) medium field (d_ε^2 and $d_\gamma^4 d_\varepsilon^4$)

$$(a)\ \mu_{\text{eff}}^2 = \frac{3\{0{\cdot}625x + 6{\cdot}80 + (0{\cdot}125x + 4{\cdot}09)\exp(-3x) - 10{\cdot}89\exp(-9x/2)\}}{x\{5 + 3\exp(-3x) + \exp(-9x/2)\}}$$

$$(b)\ \mu_{\text{eff}}^2 = \frac{3\{5x + 15 + (x + 9)\exp(-2x) - 24\exp(-3x)\}}{2x\{5 + 3\exp(-2x) + \exp(-3x)\}}.$$

(1) ^3F, T_1; λ negative. (2) $d_\gamma^4 d_\varepsilon^4$, $^3T_1$; λ negative. (3) ^3F, T_1; λ positive. (4) d_ε^2, $^3T_1$; λ positive

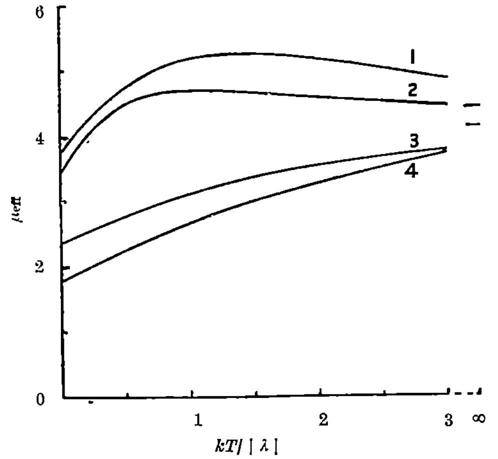

Fig. 3. μ_{eff} versus $kT/|\lambda|$ for Cr^{3+} (tetrahedral, λ positive) and Co^{2+} (octahedral, λ negative). (a) weak field (^4F) and (b) medium field (d_ε^3 and $d_\varepsilon^5 d_\gamma^2$)

$$(a)\ \mu_{\text{eff}}^2 = \frac{3(3{\cdot}15x + 3{\cdot}92 + (2{\cdot}84x + 2{\cdot}13)\exp(-15x/4) + (4{\cdot}7x - 6{\cdot}05)\exp(-6x)\}}{x\{3 + 2\exp(-15x/4) + \exp(-6x)\}}$$

$$(b)\ \mu_{\text{eff}}^2 = \frac{3\{5{\cdot}6x + 4{\cdot}32 + (3{\cdot}6x + 2{\cdot}347)\exp(-5x/2) + (4x - 6{\cdot}667)\exp(-4x)\}}{x\{3 + 2\exp(-5x/2) + \exp(-4x)\}}$$

(1) ^4F, T_1; λ negative. (2) $d_\varepsilon^5 d_\gamma^2$, $^4T_1$; λ negative. (3) $d_\gamma^2 d_\varepsilon$, $^4T_1$; λ positive. (4) ^4F, T_1; λ positive

From Penney and Schlapp it can be shown that the orbital wave functions of the T_1 orbital triplet (which lies lowest or highest according to the configuration and the sign of the ligand field) from an F term in a cubic ligand field are:

$$\psi_1 = \frac{1}{\sqrt{24}}(\sqrt{15}<3| + 3< -1|),\ \psi_2 = <0|,\ \psi_3 = \frac{1}{\sqrt{24}}(\sqrt{15}<-3| + 3<1|),$$

where $<n|$ indicates the d-orbital wave function of the free ion with $M_l = n$. They are combined with spin wave functions corresponding to $S = 3/2$ for ^4F and $S = 1$ for ^3F. It is not possible to assign an effective value to L here, but it can be shown that for $kT/\lambda \rightarrow \infty$, $\mu_{\text{eff}} \rightarrow \sqrt{\{4S(S + 1) + 4{\cdot}5\}}$. For the medium field configurations $(d_\varepsilon^m d_\gamma^n)$ the orbital wave functions corresponding to the weak field ones are:

$$\psi_1 = < -1|,\ \psi_2 = \frac{1}{\sqrt{2}}(<2| - < -2|),\ \psi_3 = <1|,$$

taken with the same spin wave functions. Here the effective value of L, L', is 1 and $\mu_{\text{eff}} \rightarrow \sqrt{\{4S(S + 1) + L'(L' + 1)\}} = \sqrt{\{4S(S + 1) + 2\}}$ as $kT/\lambda \rightarrow \infty$. These latter wave functions also apply to the orbital triplet T_2 resulting from the splitting of a D state by a cubic ligand field; here, spin wave functions corresponding to $S = \frac{1}{2}$ and $S = 2$ are required, respectively, for the ^2D and ^5D terms which arise.

In Fig. 4 the splittings which occur when the orbital triplets form the ground-terms are given by (*a*) the cubic ligand field, (*b*) the spin-orbit coupling, and (*c*) the magnetic field in first approximation. In obtaining the expressions for the susceptibilities it is necessary to consider the magnetic field in second approximation also. In Figs. 1–3 the magnetic moments for the various configurations are plotted as a function of the parameter kT/λ ($= 1/x$).

MEDIUM AND WEAK FIELD

Fig. 4. Splitting of transition-element ion ground-terms under various approximations

When the orbital triplets do not form the ground-levels, these are an orbital singlet from an *F* term (and its medium field equivalent) and an orbital doublet from the *D* terms. Then, in first approximation, the moment should be the spin-only value. However, in second approximation the spin-orbit coupling, by connecting the orbital wave functions

$$\frac{1}{\sqrt{2}}(<2| - < -2|)(d_{xy}) \text{ and}$$

$$\frac{1}{\sqrt{2}}(<2| + < -2|)(d_{x^2-y^2}),$$

introduces the correction factors:

$$\mu_{\text{eff}} = \mu_{\text{spin-only}}\left(1 - \frac{4\lambda}{10Dq}\right) \text{ for } F$$

terms[3] and medium field equivalent

$$\mu_{\text{eff}} = \mu_{\text{spin-only}}\left(1 - \frac{2\lambda}{10Dq}\right) \text{ for } D \text{ terms}^6.$$

In Table 1 the moments derived from the free ion value of the spin-orbit coupling constant and the moment at room temperature are given under the approximations outlined above, and are compared with experimental moments for the ions concerned and with the spin-only moments and with $\sqrt{\{4S(S+1) + L(L+1)\}}$. It is seen that the fact that the moments mostly lie somewhat above the spin-only value is rather fortuitous, depending in a number of cases on the existence of a favourable value of the ratio kT/λ. When other values of kT/λ are arranged, as by performing magnetic measurements at low temperatures, it is to be expected that moments considerably above or below the spin-only value should be observed for certain ions.

Table 1. MAGNETIC MOMENTS OF FIRST TRANSITION SERIES ELEMENT IONS UNDER VARIOUS APPROXIMATIONS

Ion	Ti^{3+}		V^{3+}		Cr^{3+}		Mn^{3+}		Fe^{2+}		Co^{2+}		Ni^{2+}		Cu^{2+}

* oct. = octahedral; tet. = tetrahedral. † A range of values is found.

For those ions where the difference between the medium and weak field moments at room temperature is significant the experimental results do not provide definite evidence of the superiority of one approximation over the other. This is anticipated on three counts: (1) the field-strength is likely to be intermediate between weak and medium, (2) the approximation of cubic symmetry is likely to fail in most complexes and (3) except where the ground-level is the 'non-magnetic' orbital singlet or doublet, the effects of spin-orbit coupling in mixing higher ligand field levels into the ground-level has been ignored, as also has the effect of bonding on the magnetic electrons. In this connexion it is necessary to repeat the warning given in ref. 8 against uncritical use of such formulæ; they should provide a valuable general guide to moments of first row transition element ions and their dependence on temperature, but may require much modification in individual cases.

Supplement to NATURE

No. 4649 DECEMBER 6, 1958 Vol. 182

WILLIAM HARVEY AND HIS CRITICS

The Circulation of the Blood

Two Anatomical Essays by William Harvey, together with nine letters written by him. The whole translated from the Latin and slightly annotated by Kenneth J. Franklin. Pp. xxiii + 184. (Oxford: Blackwell Scientific Publications, 1958.) 22*s.* 6*d.*

THE modern mind, trained to accept, at least tentatively, the latest scientific discovery, finds it hard to envisage a time when tradition was more highly regarded than truth. Yet it was so, even in the seventeenth century.

William Harvey, after demonstrating the circulation of the blood by experiments and by lectures for at least twelve years, published in 1628 his "Exercitatio anatomica de motu cordis et sanguinis in animalibus", often described as "the most important medical work ever written". Few believed Harvey's statements, and very few took the trouble to repeat his experiments in order to confirm or refute the new idea of a circulating blood-stream. Their minds were not attuned to the experimental method, of which Harvey was the first great exponent. Steeped in the teaching of Galen and the ancients, they failed to envisage "how such a circulation takes place without causing upset and mixing of the body's humours and destruction of traditional medicine", as Riolan expressed it. Any statement which contradicted the old and accepted views simply could not be true.

Harvey at first maintained a discreet silence and declined to be drawn into argument by his earlier critics. Only after a lapse of twenty-one years did he reply to the criticism of his friend Riolan in the "Two Anatomical Essays" now under consideration.

Jean Riolan, jun., of Paris, had sent Harvey a copy of his work on pathological anatomy, entitled, "Encheiridium anatomicum et pathologicum", which contained his criticism of Harvey's discovery. Unlike some of the earlier critics, Riolan was not abusive or disrespectful. Apparently seeking for a partial acceptance of the new idea which might satisfy the exponents of traditional medicine, Riolan did not wholly deny that the blood circulated, but he affirmed, or rather re-affirmed, the passage of the blood through the interventricular septum, and stated that the mesentery was devoid of any circulation. He produced no experimental evidence in support of his contention, and it is not surprising that this attempt to satisfy both sides really satisfied neither the critics nor the supporters of the new doctrine. Harvey begins his reply to Riolan with a graceful reference to the value of Riolan's book, mentioning his own interest in pathology, as shown in his writing on "medical anatomy", a work which appears to have been lost. He then proceeds to refute Riolan's statements, and to defend his original contention that "there is a circulation everywhere, and not restricted to certain parts". He admits that he has failed to discover the capillaries, but he now states, as he did not in 1628, that the heart does not re-charge the blood with "innate heat" or "vital spirits", adding "Such spirits show a common subterfuge of ignorance". Harvey must have felt how obstinate were his old-fashioned opponents when he wrote, "How hard and difficult it is to teach those who have no experience the things in which they lack such or have no sensible knowledge".

The eight letters which follow the anatomical essays to Riolan, though much shorter, are no less interesting. All were written during the last few years of Harvey's life, and they show his nobility of character and his gift of kindly friendship. To Nardi he wrote in 1653, "I am myself almost an octogenarian, and, although my physical powers are tottering with my body broken, yet with my mind active I give myself up gladly to studies of this sort", and to his Dutch friend, Jan Vlackveld, just before his death in 1657, he confessed himself "ripe in years but also—let me admit—a little weary" and "entitled to ask for an honourable discharge".

Prof. Kenneth Franklin, who embodies the unusual combination of a master of Latin and a professor of physiology (at St. Bartholomew's Hospital, where Harvey himself taught), made a most valuable contribution to the Harveian tercentenary celebrations last year by his translation of "De Motu Cordis" (see *Nature*, 180, 449; 1957). He has now added to his high reputation by giving us, in deft and elegant English, a modern translation of the essays to Riolan and the letters, under the title "De Circulatione Sanguinis", a fitting, and indeed essential, sequel to the earlier work, showing a more mature Harvey whose outlook had been ripened by years of further meditation and experiment.

"De Circulatione Sanguinis", 1649, is by no means a mere postscript to "De Motu Cordis", 1628, and perhaps it is unfortunate that the two books, bound together in what has been hitherto the standard translation by Robert Willis, now appear separately. Even the intelligent student, viewing them casually, might well regard them as the same book, so similar are they in format and title. The two are so intimately interwoven that they surely deserve to share one cover, and it is hoped they may do so in future editions. The Latin text forms the second half of the volume. Paper and printing are admirable, as also are the annotations and bibliography. Two rather rare illustrations show Riolan at work, and Harvey, in his later years, while a lovely coloured frontispiece of Charles, Prince of Wales, by William Dobson, commissioned by King Charles I and presented to Harvey, has been reproduced from the original painting in the Scottish National Portrait Gallery. Prof. Franklin has certainly revealed a new Harvey to the modern reader. His two delightful translations of the greatest of medical classics depict not only the discovery which inaugurated a new era in medicine but also the dawn of the experimental method and the demonstration of its value in the hands of the noble, erudite and intensely human William Harvey.

DOUGLAS GUTHRIE

PERCEPTION AND COMMUNICATION

Perception and Communication

By D. E. Broadbent. Pp. v+338. (London and New York: Pergamon Press, 1958.) 55*s.* net.

BROADBENT has written what is in many ways a most admirable book. Those who are interested in the analysis of human performance in the artificial environments created by technological advance will find in it a valuable and intelligent summary of the various subjects which have been investigated, many at the Medical Research Council Applied Psychology Unit at Cambridge of which Broadbent is the director. However, it would be misleading to suggest that he has given us a mere factual digest. He performs the difficult and unusual task of relating these findings in the applied fields to the problems which have traditionally been regarded as more fundamental, and shows with great skill that applied research does have theoretical importance. The field he covers in this process ranges from the effects of noise on human skill to latent learning in rats. Regarded as a review and a stimulant to thought, the book is first-rate. However, it can also be read as a theoretical contribution to general psychology. Here, Broadbent has many provocative and interesting suggestions. But there are various places where it seems that a more serious intellectual effort might have led the author to theories of greater depth. He tends to treat theories merely as different jargons; and this is what one might conclude from the way he uses them. His use of the terms of information theory, highly precise in their own context, is somewhat loose and without any clear purpose. His own filter theory is rather like the Freudian theory of memory. It accounts only for our failures while our successes continue by the same obliging miracle which has always served. One fears also that logically the filter theory resembles in many ways the explanations of faculty psychology. The abilities or properties of the whole man are explained by postulating entities each of which displays one of those abilities or properties. The statements of such theories are simple translations of the generalization which they are invoked to explain.

The interpretation of the experimental evidence necessarily precedes the framing of theories, as many results are not what they seem. Theorizing, particularly in psychology, is made difficult because the skill and hunches of experimentation are virtually impossible to convey to those who have not had practical experience. It is very easy to get the accent wrong. Animal experimentation is especially hard to evaluate. Though incomparably better than some of the engineers who have attempted to frame theories of animal behaviour, Broadbent's reviews and suggestions in this field are less felicitous than elsewhere. In his chapter on extinction the important problem of latent extinction is left untouched. Whatever the reason for this omission the experimental data in this field invalidate any such approach to learning or extinction as Broadbent's or Uttley's. The question of goal-extinction has been brought into prominence recently by Moltz, who attempts to solve it in Hullian terms.

Nevertheless, the shortcomings on the animal side are not serious for Broadbent's main thesis of filter theory, which must be judged by its usefulness in thinking about human performance. It might therefore be regarded as curious that no time is spent on the clinical material relevant to such subjects as attention or memory. A much firmer case could be made for the relevance of psychopathology rather than of animal psychology to Broadbent's ideas. Indeed, many of his problems are posed in an acute way in clinical psychology and the brilliance of Breuer's speculations concerning their solution has not been surpassed.

But perhaps these criticisms are not entirely fair. Broadbent in the book does concentrate mainly on the fields where he himself has made important contributions (with the exception of animal work). We cannot therefore reproach him too much for not attempting more. Secondly, it is not entirely clear for whom this book is written. The criticisms would apply in their full force if the book was meant to be a technical contribution. But taken as a more popular volume the force of any of the above strictures is largely lost, and we read with interest a scientist of imagination and intelligence writing about the many subjects to which he has made outstanding contributions.

J. A. DEUTSCH

EVOLUTION OF THE HUMAN MIND

Man's Emerging Mind

Man's Progress Through Time—Trees, Ice, Flood, Atoms and the Universe. By Dr. N. J. Berrill. Pp. xii+308. (London: Dennis Dobson, Ltd., 1958.) 21*s.* net.

THE Primates, feeding in the high, evergreen trees of warm, wet lands, could produce young at any season, but only one, or sometimes two, babies could cling to the mother as she climbed. They could make noises and groom themselves or one another without too much fear of the great cats below, ready to pounce. Swinging arms left legs freer for occasional and, eventually, persistent ground-walking, and the growing head and diminishing snout made this easier as the skull came to rest on the backbone—a very important matter as the brain grew towards its weight of 1,300–1,400 gm. The genes for snout-reduction seem rather specially linked with those for forward-looking eyes, and all these changes were such as Nature would select among groundlings. Development of hair is late in pre-natal life, and its competition with brain-development helped to make men's bodies almost hairless, with advantages in increased sensitivity and decreased parasites. The maintenance of hair on the head has proved valuable in protecting the brain from short-wave radiation, which would otherwise penetrate the thin skull of youth. Maintenance of head-hair led to its development as an ornament in women.

The decrease of body-hair helped, and was helped by, brain growth, at first subject to limits set by the birth-process, but, later, with fœtalization of the skull, continuing through an elongating infancy. Berrill hopes that further elongation of infancy, the trailing clouds of glory, as Wordsworth has it, is in store for mankind, and certainly the age of marriage has risen since Tudor times in Western Europe, and this has been a factor in intellectual activity and diversity of views.

The author might have further expanded the idea of skull growth to show that a decrease of ruggedness, and the early fixity accompanying that ruggedness, helps to account for the 'Mediterranean' dolichocephalic race-character as an evolutionary change from hyperdolichocephals, often with strong brows, who linger among Australian aborigines and elsewhere. Too recent for this book is Dr. Oakley's provisional interpretation of finds as tools of Australopithecines; but, if this becomes established, tools contributed to early brain growth. The author follows general opinion in assigning some importance to sexual selection in mankind.

The book's rapid survey of civilizations emphasizes factors of climatic change very suggestively and, of course, tentatively. The southward spread, from a zone stretching between Mersin and Meshed to the lower parts of the twin-rivers, leads on to the rise of Sumer, a prime germ-centre influencing Egypt, India, Crete, Greece and probably China as well. The unity of Nature, including the whole man, is a leading theme of this book, so the author is in the succession from Spinoza and Goethe through such thinkers of our own culture as Lloyd Morgan, Smuts, Whitehead (whom he aptly quotes) and Alexander. All separatist curtains, whether iron or bamboo or brick, or linguistic or dogmatic, are a menace. Language can condition ideas, and pressures stultify inspirations. Freedom of critical thought and research is of prime importance. There are dangers in setting workers to do specified research tasks except in applications of science; science is more than its applications, and increase of understanding is to be sought along all possible paths, converging towards a goal that is always in the future. H. J. FLEURE

HUMAN STERILITY AND FERTILITY

The Reproductive Development of the Female

With Special Reference to the Period of Adolescent Sterility. By Prof. M. F. Ashley Montagu. Pp. xvii+234. (New York: The Julian Press, Inc., 1957.) 5 dollars.

Reproductive Physiology

Comparative Reproductive Physiology of Domestic Animals, Laboratory Animals and Man. By A. V. Nalbandov. (Series of College Texts in Agricultural Science.) Pp. xi+271. (San Francisco, Calif.: W. H. Freeman and Company; London: Bailey Bros. and Swinfen, Ltd., 1958.) 6.75 dollars; 58*s*.

BOTH these books come from the United States, and they both deal with different aspects of the subjects of sterility and fertility. The first is the more highly specialized of the two works. Prof. Ashley Montagu is an anthropologist as well as an anatomist and he has long been interested in a subject which has puzzled a great many anthropologists, namely, why girls who belong to primitive societies which grant a great deal of sexual freedom to their young people very seldom become pregnant. Malinowski directed attention to this fact in his book, "The Sexual Life of Savages" (published in 1929), after his return from living with the Trobriand Islanders. He writes: "It is very remarkable to note that illegitimate children are rare. The girls seem to remain sterile throughout their period of licence, which begins when they are small children and continues until they marry; when they marry they conceive and breed, sometimes quite prolifically. . . . I was able to find roughly a dozen illegitimate children genealogically in the Trobriands, or one percent". The young islanders shared sleeping mats in the communal sleeping hut to which they repaired at night: they knew nothing about contraceptive methods and they did not practise coitus interruptus. Why did the young girls so seldom become pregnant?

This is no longer a puzzle. Prof. Montagu, the author of the book under review, first published the results of his investigations of the subject in 1946 in a volume entitled "Adolescent Sterility". In the present book he adds fresh evidence of the existence, in all races, of a period of post-pubertal sterility. Previously, it was assumed that the establishment of menstruation was an indication that a woman was now able to procreate, but this is now known to be untrue. There is usually an interval of about three years before conception is likely to take place. It is also clear that even after women have passed this interval they are likely to be less fertile than they will become a few years later. There are several possible explanations of this period of relative infertility, the commonest being failure of the monthly ovulation and imperfect nidation of the fertilized ovum.

The human observations on this subject have been supplemented by similar observations on a number of different animals ranging from mice to chimpanzees. It is interesting to know that although exact observations on the adolescent male are more difficult to obtain, there are good reasons for believing that a similar period of sterility exists also in him. Prof. Montagu quotes Kinsey as stating in his report that "unpublished data gathered by the group study of sex behaviour at Indiana University indicate that there may be a period of some years of adolescent sterility in the human male". This idea is likewise supported by Webster and Young's investigation of the fertility of young male rats and guinea pigs.

Dr. A. V. Nalbandov, a lecturer in the agricultural sciences at the University of Illinois, in his book makes a very wide and complete survey of the subjects of fertility and sterility. His observations have been made on animals, but they throw light also on human fertility and sterility, and this makes his book of considerable importance to gynæcologists and medical men generally. In veterinary as in human practice, one of the difficulties which the research worker encounters is that the sterility or infertility problem is usually a multi-dimensional problem. That is to say, it is due generally to the existence of a number of different factors which may act singly but which usually react on each other so as to render breeding impossible. For example, female ewes which suffer from a reduced fertilizability of their ova often display an increased mortality-rate in the developing embryo. The problem to be dealt with is consequently often a highly complicated one.

Artificial insemination is being more widely used by veterinary surgeons, and Nalbandov attributes this partly to an extended use of semen diluters and partly to better facilities for the storage of semen. But there is a great difference in the viability of the sperms of different animals. While human, bull and chicken semen all withstand freezing at −79° C. and prolonged subsequent storage, semen from a stallion cannot be subjected to this treatment. Indeed, stallion semen loses its fertilizing capacity at ordinary temperatures within forty-eight hours of ejaculation. This is unfortunate, for it makes impossible the use of artificial insemination where it would prove most convenient, namely, as a means of avoiding the transport of valuable thoroughbred stallions. Although bull semen can be stored far better than stallion semen, there is reason to believe that "germ cells age and thus become physiologically less vigorous, and that their senility may be one of the main causes of embryonal mortality in both mammals and birds". Dr. Nalbandov stresses the importance of timing matings or insemination in domestic animals and in man "in such a way as to immunize the deleterious effects of the ageing of the ova and sperm cells".

Dr. Nalbandov's aim has been to give as full an account as possible of the "comparative reproductive physiology of domestic animals, laboratory animals and man", and the book he has written is the most complete work on this subject which the reviewer has, as yet, encountered. The various chapters contain many references to articles and books which provide departure points for further reading on these subjects. Both these new books should become standard works on their respective subjects.

KENNETH WALKER

THE ARRHYTHMIAS

Rhythmusstörungen des Herzens

Systematik—Ursache und Klinische Bedeutung—Therapie. Von Prof. Konrad Spang. Mit beiträgen: Die Morphologie des Reizleitungssystemes, ihre Orthologie und Pathologie. Von Prof. W. Doerr. Physiologie der Herzirregularitäten. Von Dr. W. Trautwein. Pp. xvi + 548 und ein Tafelanhang mit 228 Abb. (Stuttgart: Georg Thieme Verlag, 1957.) 148 D.M.

THE length of this book on a relatively circumscribed subject may at first alarm the reader, but he will be quickly reassured when he begins to study it, for it is clearly arranged and the style is lucid.

The author has set himself the task of re-awakening interest in the arrhythmias. After the initial enthusiasm following the appearance of Sir Thomas Lewis's book and that of Wenckebach and Winterberg, interest has lagged, since only a few arrhythmias are really of clinical importance. The author believes them to be often of greater clinical importance than is sometimes recognized to-day, but at the same time admits that in many cases the only reward of laborious study may be a better understanding of the disordered physiology.

To a British reader the collection of illustrative electrocardiograms at the back of the book, divorced from the text, is a drawback, since inclusion of a suitable illustration on the same page as the text makes for clearer exposition. On the other hand, diagrammatic representation of the mechanism of many of the complicated arrhythmias, such as parasystole, is included in the text and the notation of these diagrams could scarcely be improved, explaining at a glance what neither text nor electrocardiogram could convey simply. The diagrams of abnormal spread of conduction through the heart are also very clear and helpful.

The newer theories of the genesis of some of the arrhythmias, such as atrial fibrillation, are fully discussed. Rhythm changes during special cardiac investigations and during operations on the heart under hypothermia are briefly touched on. In addition, the chapters on treatment include more recent methods, such as the cardiac pace-maker and the defibrillator.

This book attempts to wed academic interest in the arrhythmias to fuller understanding of their clinical importance, and in this it largely succeeds.

J. P. D. MOUNSEY

TREATISE OF ZOOLOGY

Traité de Zoologie

Anatomie, Systématique, Biologie. Publié sous la direction de Prof. Pierre-P. Grassé. Tome 13: Agnathes et Poissons—Anatomie, Éthologie, Systématique. Premier Fascicule: Pp. viii + 924. Deuxième Fascicule: Pp. viii + 925–1812. Troisième Fascicule: Pp. vii + 1813 + 2758. (Paris: Masson et Cie., 1958.) Chaque fascicule, broché, 12,000 francs; cartonné, 13,000 francs.

IT is ten years since the first volume (Vol. 11 in the series) of the "Traité de Zoologie" appeared, and now we have to welcome Vol. 13, the ninth to be published, which is devoted to the Agnatha and Pisces. The total number of volumes in the series is to be eighteen, so that approximately half the work has now been published although there may be rather less to come as some of the larger classes have already been dealt with. Zoologists the world over have come to know what to expect and to look forward to new additions to the treatise. The present volume, with its 2,758 pages, is so large that it has been divided into three almost equal fascicles, each as large as an ordinary volume, containing 924, 888 and 946 pages, respectively. As in all previous volumes, this one is generously furnished with illustrations which form an important part of the work.

The last text-figure is numbered Fig. 1889, but this is misleading and there has been some confusion in numbering, for Fig. 219 on p. 419 is followed on p. 434 by Fig. 245, and Fig. 1043 occurs on p. 1453 and again on p. 1471, so that the actual number is 1865. There are six plates in full colour. This, as in former volumes, does not give a fair impression of the wealth of illustrations, for a number of the figures contain several drawings which may even be on separate pages; for example, Fig. 378 occupies the whole of pp. 588 and 589 and nearly all of p. 590, Figs. 81 and 82 take up five complete pages and the best part of two more. These last two figures furnish excellent examples of a combination of line and colour, not common in text-books, but which in these and twenty-five others has been employed with telling effect. The great majority of the figures are line-blocks or half-tone or a combination of the two, and are on the whole very good although a few half-tones, for example, Figs. 720, 849, 1474 would be much improved if the background were cut out and the impressions were deeper. It is a pity that in the main systematic part (Fascicle 3) so many of the attractive illustrations give no indication of the magnification or reduction, nor is the size stated in the text. There is a certain lack of consistency in nomenclature, for example, sometimes *Lepisosteus* is used (deliberately) and sometimes *Lepidosteus*; sometimes *Scylliorhinus* and at others *Scyllium*.

Twenty-two authors, fifteen of them from Paris and each a specialist in his own field, contribute to the volume, thus ensuring an authoritative and up-to-date treatment. It has been customary for the authors to be chosen from French-speaking zoologists, but an exception has been made in the present instance, and the section devoted to the ostracoderms, fossil cyclostomes (pp. 173-425 in Fascicle 1) is by an eminent authority on the group, Prof. E. Stensiö of Stockholm. This is probably the best general account of the ostracoderms available. It is well illustrated and contains, *inter alia*, a number of half-tone reproductions of actual holotypes. The magnification of the illustrations is almost invariably given, thus conveying an idea of size as well as appearance. There is a slip in the footnote on p. 256, where 'Dr. E. J. Whitte' is printed for what should obviously be Dr. E. I. White. The systematic treatment of the class Osteichthyes follows more or less orthodox lines, so that, as the fossil forms are included with the living throughout, the Crossopterygii come at the end. The last subdivision is a new super-order, the Actinistii containing the single order Coelacanthiformes, which has a single living genus *Latimeria*. While there are references to certain structures in *Latimeria chalumnae* (the only living species in the genus) in the general anatomical treatment of the bony fishes, the more extended account of it is to be found on pp. 2553–2597. The story of the discovery by Prof. J. L. B. Smith of this remarkable form is well known to all zoologists. The authors of this section are Prof. J. Millot and M. J. Anthony of the Natural History Museum in Paris, where there are ten well-preserved specimens. Not only is it a survivor of a group considered to have become extinct in the Cretaceous, but also the Crossopterygii occupy a most important systematic position. The coloured illustration on Plate V gives a clear impression of the appearance of the creature. The description covers a considerable amount of ground in a general way and is illustrated with good original photographs. In view of its rarity and great interest it is being thoroughly investigated by a team of workers, and a full account of this creature has only become available very recently.

Ninety pages of index and table of contents complete a volume which is well worthy of a place in a series widely known for its general excellence. It will remain indispensable for a long time.

C. H. O'Donoghue

TRANSPORT ACROSS CELL MEMBRANES

Metabolic Aspects of Transport across Cell Membranes

Edited by Q. R. Murphy. Pp. xxiv + 379 + 11 plates. (Madison, Wisconsin: University of Wisconsin Press, 1957.) 7.50 dollars.

The format, printing and production of illustrations in this volume are excellent, and the subject-matter summarizes a large amount of information concerning active transport in various tissues. Although the production of this volume was delayed, any notable advances made in the intervening time have been usually included in the proofs or as footnotes therein up to the year 1957.

Eleven formal papers were read, with intercurrent discussions with panel members at the symposium reported. It opened with a paper by Dr. E. F. Adolph on "Regulation in Fluid Exchange" with reference to the whole organism. He was followed by Dr. D. C. Darrow on "Some Aspects of Ion Exchange in Clinical Medicine". Dr. H. H. Ussing's communication was on "General Principles and Theories in Membrane Transport" and Dr. M. B. Visscher's on "Transport of Water and Electrolyte across Intestinal Epithelia".

In the section on ionic transfer in muscle and nerve, papers were read by Dr. E. J. Conway on "Membrane Equilibria in Skeletal Muscle and the Active Transport of Sodium"; by Dr. Silvio Weidman on "Transport of Ions across Cardiac Membranes"; and by Dr. A. M. Shanes on "Ionic Transfer in a Vertebrate Nerve". This was followed by a discussion with Drs. Fenn and Gerard, acting as co-chairmen. Dr. Fenn dealt with buffering mechanisms in relation to acidic treatment either of isolated amphibian muscle or after injection into the whole animal with particular reference to potassium, sodium and chloride exchanges. Dr. Wilde gave an account of his elegant 'effluograph' technique, with which the release of potassium in a single beat of the turtle's heart could be measured accurately. He also developed some clinical applications of the Conway theory. Dr. Brink communicated experimental results mainly concerned with the correlation between loss of potassium and uptake of oxygen in frog nerve. Dr. R. Gerard put forward the views of Dr. G. Ling (who was unable to attend the symposium) with respect to the distribution of potassium and sodium ions inside and outside cells. This was answered by Dr. Conway, who had criticized Dr. Ling's views in his paper. This material was sent later to Dr. Ling, who replied, and a final rejoinder was made by Dr. Conway.

In the section on transport across renal epithelium, Dr. R. W. Berliner read a paper on "Some Aspects of Ion Exchange in Electrolyte Transport by the Renal Tubules". Exchanges of potassium, sodium and hydrogen ions were chiefly considered. The view that the carbonic acid system was responsible for urinary acidification was effectively dealt with, and acidification attributed to sodium and hydrogen ion exchanges. This agrees with the 'redox pump' theory, so named by Dr. Conway, which would in turn interpret the occurrence of carbonic anhydrase in the renal nephrons.

Reference was also made to the evidence pointing to the total re-absorption of the glomerular potassium in the proximal convoluted tubules, and its excretion of potassium lower down the nephron. In this context attention may be directed to the recent experiments of Dr. Morel (*Helv. Physiol. et Pharm. Acta*, **3**; 1956) working with radioautographs of kidney slices after injections of labelled potassium, which appear to demonstrate elegantly such potassium exchanges.

A rather long and occasionally lively discussion followed, the panel members being Dr. Pitts (chairman) and Drs. Davies and Berliner. In this, Dr. Davies presented some new evidence with respect to potassium and sodium exchanges in kidney slices. This discussion was followed by another on the transport of organic compounds across renal epithelium, the panel members being Dr. Shideman (chairman) and Drs. Farah and Beyer. Experimental results of much interest were presented and discussed.

In the section on the secretion of gastric hydrochloric acid, Dr. Davies read a paper on "Gastric Hydrochloric Acid Production—the Present Position". Dr. H. W. Davenport read one on "Metabolic Aspects of Gastric Acid Secretion" and Drs. W. S. Rehm and W. H. Dennis presented "A Discussion of Theories of Hydrochloric Acid Formation in the

Light of Electrophysical Findings". A discussion followed, the panel members being Dr. Pitts (chairman) and Drs. Hogben, Davenport, Davies and Rehm.

In the discussion a lively controversy developed between Drs. Davenport and Davies concerning the true ratio of hydrochloric acid secreted to the oxygen uptake concerned therewith. It may be noted that both workers accepted a redox origin for the hydrogen ions, or the redox pump theory, but, whereas Dr. Davenport considered the upper limit of the ratio to be 4·0, Dr. Davies argued for its being greater than 4·0, with a back-feed of electrons. This controversy is dealt with rather fully by Dr. Conway in a paper on "The Redox Pump Theory and Present Evidence" at a symposium held at Saclay, Paris, 1958. From a new approach it was shown, using Davenport's numerous results with *Rana pipiens*, that it could be confidently concluded that in this species the upper limit of the ratio is 4·0, and the evidence for a similar conclusion from Davenport's mouse results is very strong.

The symposium ended with a discussion on the "Correlation of Clinical Problems and Basic Information relating to Membrane Transport". The panel members were Dr. Visscher (chairman) and Drs. Adolph, Elkington, Darrow, Streeten and Ussing. The chief contributions, with experimental results, were made by Drs. Elkington and Streeten.

BIOLOGICAL D-DAYS

The Ecology of Invasions by Animals and Plants

By Charles S. Elton. Pp. 181+50 plates. (London: Methuen and Co., Ltd., 1958.) 30*s*. net.

THIS is rather a deceptive book because at first it might seem little more than a lightly written, easily read and pleasantly produced account of some of the more outstanding consequences of introducing alien plants and animals where they do not belong. All this indeed it is, but it is also something much more because in the course of it Mr. Elton brings to the reader's notice more than one matter of prime biological importance. As he himself says in the preface, he has tried to bring together ideas from three different streams of thought: faunal history, ecology, and conservation, and on each of these he has something valuable to say.

In discussing the first of the three he develops the idea that before the Cretaceous not only were climatic conditions more generalized but also world-geography was more continuous, so that organic groups, as they evolved, more easily became world wide. Then and since, however, sea transgressions increased the isolation of continents so that each tended to develop its own fauna of birds, mammals and other recent groups. It is this continentality in distribution that is being so rapidly broken down by man to-day. Whatever the geophysical merits of this may be (and it is odd that there seems no mention of theories of continental drift) it is a piece of lively thinking and therefore welcome.

As an ecologist the author is chiefly concerned to make the point that the richer in forms and species a natural community is the greater the inherent stability it has and the better able it is to absorb shocks from outside. He rightly mentions tropical rain-forest as a supreme example of this. No doubt most biologists to-day realize, in some measure at least, that Nature is not a chaos of warring factions but a complex and delicate system of balances in which all share and to which all contribute, but this still cannot be too plainly stated and often repeated.

It is in considering conservation that Mr. Elton does his chief service—by putting fairly and squarely one of the really ultimate questions of biology, namely, what is going to happen when man has finally destroyed (as he certainly will, barring impediments) all the natural floras and faunas of the world. To get the right answer before this happens may make all the difference to the human race.

The book has some beautifully clear maps, but it is a pity that Mercator's projection is used for depicting distribution, a purpose for which it is most unsuitable. To take an example, the genus *Rhododendron* (Fig. 48) cannot possibly occupy, in continental North America, an area greater than that of the whole of Africa; nor is the gap between its North European and Asiatic areas equal to the distance from the Cape to Cairo.

RONALD GOOD

VIRUS STRUCTURE AND FUNCTION

Advances in Virus Research

Edited by Kenneth M. Smith and Max A. Lauffer. Vol. 4. Pp. ix+340. (New York: Academic Press, Inc.; London: Academic Books, Ltd., 1957.) 8 dollars.

THE dissection of viruses into their structural and functional entities has led to many exciting advances in current problems of virology. Although this volume begins with an excellent essay by Andrewes on the more philosophical topic of virus evolution, most of the contributions are concerned with various aspects of the anatomy and enumeration of virus particles and their mode of attachment and penetration into host cells.

The contributions by Hershey and Tolmach summarize much of the recent knowledge on the biochemical, genetic, structural and functional properties of bacterial viruses. Tolmach has admirably reviewed the mechanism of phage binding and the ensuing processes of 'penetration' and 'injection' of the viral deoxyribonucleic acid. This chapter is not specifically devoted to bacteriophages, yet it serves to emphasize how much more is known about their attachment and penetration than is known for animal viruses. One of the fascinating reactions outlined in Tolmach's article is the increased permeability following phage infection and the 'resealing' or reversal of this change in permeability. The favourable position of the virologist working with bacteriophages is further illustrated by the results of Benzer's experiments on genetic fine structure, mentioned in Hershey's review.

When we depart from the experimentally ideal situation where the ratio of particles to infective units is 1 (as with phages), the problems of measuring virus concentrations become more acute. The chapters by Isaacs and Yarwood make it abundantly clear that in inocula of animal and plant viruses, the particle counts greatly exceed the numbers of successful infections. With mechanical transmission of plant viruses, various treatments can increase the efficiency of infection. There seems to have been little attempt to seek an explanation for some of these effects. Indeed, at present there is no obvious explanation why such large numbers of animal and plant viruses are required to initiate an infection. As Isaacs justly points out, blaming the failure to infect on "non-infective" particles or on "insusceptible" cells, falls into "the category of moral rather than scientific judgement". The enormous discrepancy between particle counts and infectivity titrations raises the problems of recognizing 'viruses' in the electron microscope. Pirie's chapter on the "Anatomy of Tobacco Mosaic Virus" will act as a refreshing antidote to those who infer that the size, shape and properties of the tobacco mosaic virus particle can be rigidly defined.

A diversion from the main theme on the structure, surface immunology and penetration of viruses is provided in the excellent chapter on the "Effects of Non-Ionizing radiations on Viruses" which, on the admission of the author, deals with effects on the biological activities of the virus rather than with any alteration of the component protein and nucleic acid parts.

The articles in this volume are presented in a lucid style, and they make good reading. There is, however, rather more duplication of information than one had hoped for. Virologists' addiction to 'the glossary' is amply illustrated in this book. The origin of this practice is difficult to justify as the terms used are those of general science. If a glossary proves indispensable, then I would at least prefer a non-classical presentation so that I should know, beforehand, the meanings of the terms to be used, rather than leave it until it was too late. M. R. J. SALTON

AN INTRODUCTION TO PHYSIOLOGY

Cell Physiology

By Prof. Arthur C. Giese. Pp. xviii + 534. (Philadelphia and London: W. B. Saunders Company, Ltd., 1957.) 70*s*. net.

WHAT is cell physiology? Since every organism is made up of cells, cell physiology could include the whole of physiology. If cell physiology is intended to cover what I would prefer to call the 'general physiology of the cell', it can be limited to those aspects of physiology which are common to all cells, such as water and salt relations, enzyme action in general, respiration, and, of course, the physical and chemical properties of protoplasm on which these processes depend. Prof. A. C. Giese, in his introductory chapter, makes it clear that what he calls cell physiology is of wider scope than this, for he says that the cellular physiologist is interested in nutrition, response to environment, growth and reproduction.

This would not seem to leave a great deal, but actually most of the book does deal with the general physiology of the cell, including the properties of protoplasm, cell division, cell membranes and the passage of water and dissolved substances through them, enzyme action and respiration. However, in line with Prof. Giese's wider conception of cell physiology, in a section devoted to nutrition, there is a chapter on photosynthesis which, although fundamental for nearly all life, is not to be regarded as within the scope of general physiology, since it is a function limited to the chlorophyll-containing cell. Again, a whole section of five chapters is concerned with irritability and response. Thus the title of Prof. Giese's book seems to me to be a little misleading; a title such as "An Introduction to General Physiology" might, perhaps, have given a better idea of its contents. Indeed, according to the preface, this is what it is intended to be, for we are told that the book is based on a set of lectures given at Stanford University and that logical sequels to the course are "classes in plant physiology, comparative animal physiology, mammalian physiology and bacterial physiology".

As an introduction to physiology the book undoubtedly fulfils its purpose. Physical and physico-chemical principles necessary for an understanding of physiological processes are dealt with adequately, and in this connexion the chapters on acidity and *p*H, and on temperature and life, may be particularly noted. As regards the discussions on the various aspects of cell physiology, I can call to mind no other book designed for students beginning to study physiology which gives such an up-to-date account of these. The book is clearly written and should be of value to the students for whom it is intended.

The illustrations are clear and adequate and many are original, but why is the picture of Brownian movement on p. 10 attributed to Steel's "Physical Chemistry and Biophysics" of 1928? This figure appeared in the late Sir William Bayliss's "Principles of General Physiology" published in 1915, where it was attributed to Perrin, whose original paper was published in 1909. W. STILES

TEA

Tea

By Dr. T. Eden. (Tropical Agriculture Series.) Pp. xvi + 201 + 73 Photographs. (London: Longmans Green and Co., Ltd., 1958.) 35*s*. net.

IT is not known when tea drinking commenced but it was a custom of China even before the Christian era. The Japanese took up tea drinking from the Chinese, and Arab traders brought a knowledge of it to the West. Jesuit missionaries brought a further knowledge of it to the West in the sixteenth and seventeenth centuries. The first arrival of commercial tea in London was between 1650 and 1655. Coffee drinking and the first English coffee houses date from about the same time. To-day the estimated consumption of tea in the United Kingdom is about 10 lb. per person per annum, while that of coffee is about 2 lb. A notable trend in recent years has been the great increase in tea drinking by some countries, especially by the local populations in many parts of the Indian subcontinent and Africa.

As up-to-date books on coffee (by Haarer) and cocoa (by Urquhart) have recently been written, it is fitting that one on tea should now appear. The author is familiar with tea production in many lands and has had a wide experience with the crop, first with the Tea Research Institute of Ceylon and later as the director of the Tea Research Institute of East Africa. All aspects of tea cultivation and preparation are dealt with by the author, and the fundamental agricultural and technological principles of the industry discussed. Much of the information presented is new or the result of recent research, particularly in such sections as those dealing with pests and diseases, manuring and vegetative propagation. The book is well written and well illustrated, and should prove of value wherever tea is grown, and as a reference work. Altogether a very great deal of information has been compressed into a comparatively small space. F. N. HOWES

ENZYME KINETICS

The Chemical Kinetics of Enzyme Action

By Prof. Keith J. Laidler. Pp. vii+419. (Oxford: Clarendon Press; London: Oxford University Press, 1958.) 60*s*. net.

ENZYMOLOGY lies between the fields of physical and biological chemistry. Consequently, there is the need for a book to acquaint scientists from each discipline who are interested in enzymes with the basic principles of the other. In his preface, Prof. Laidler states that "this book has been prepared with the idea that it might be helpful to collect together some of the main results and concepts that have developed on the physical side". Because of this emphasis this book is, in the opinion of the reviewer, more suitable for the biochemist wishing to learn about the application of physico-chemical methods to the problem of enzymes than it is to a physical chemist interested in enzymology.

In the first chapter there is an elementary and limited introduction to enzymes for the physical scientist, and this is supported by some of the material of the final chapter concerning protein denaturation. Providing the reader does not expect to learn much about the biochemistry of enzymes from it, the book fulfils its purpose well.

The author is well known for his contribution to chemical kinetics, and in this volume he presents a clear and skilful account of this subject. The treatment is thorough, beginning with a sound introduction to kinetic principles followed by their application to very many interactions between enzyme, substrate and inhibitors. One topic which has been overlooked is a reaction between enzyme and substrate which occurs in more than two kinetically distinguishable steps.

It is regrettable that there is no standard nomenclature in the literature for the description of enzyme-catalysed reactions. Although the treatment in this book is generally consistent there are, unfortunately, a few examples of enzyme reactions for which individual algebraic analysis is required. The reciprocal of the Michaelis constant is used. This is advantageous in that it provides a direct measure of the affinity of enzyme for substrate; but it is unlikely that this change will be popular with many enzymologists. There are a small number of errors in the kinetic expressions, generally due to confusion between rate constants—for example, k_{-1} is sometimes written for k'_{-1}.

Forty-six pages are devoted to the important effect of hydrogen ion concentration on enzymatic activity. The theory is well illustrated by recent examples from the literature, though one might have chosen examples which have given kinetic data of greater precision. Such speculation makes interesting reading, but may, of course, be subject to revision in the light of new work.

The outstanding questions of enzyme action, efficiency and specificity receive brief but stimulating mention. Then follows a review of methods, kinetic and otherwise, which have been of assistance in elucidating enzymic reaction mechanisms.

The author devotes four chapters (110 pages) to a small number of the enzymes which have been subjected to most study, and reviews knowledge about them derived from kinetic and other evidence. The hydrolytic enzymes are treated in some detail; unfortunately, some of the tabulated data (for example, Tables 22 and 35) are not the best available Many values given are now known to be in error The oxidative enzymes and catalase and peroxidase receive brief mention. This review of current work is a difficult task in such a rapidly developing field, and it has not been assisted by the long time-lapse (two years) which appears to have occurred between completion of the manuscript and publication. This is partly compensated by including an appendix of references, some for 1958. Unfortunately, most topics can receive only a curt statement in this.

The emphasis in this volume has been placed on kinetic principles rather than individual enzyme systems, so that most chapters will not become too rapidly out of date. The book can be warmly recommended to biochemists; it is less suitable for physical chemists and others working in the field, although they, too, may find it useful to have as a reference book to specialized kinetic treatments necessary for enzyme reactions. B. R. HAMMOND

INSECTICIDES

Die Insektizide

Chemie, Wirkungsweise und Toxizität. Von Dr. Werner Perkow. Pp. viii+384. (Heidelberg: Dr. Alfred Hüthig Verlag, 1956.) 28 D.M.

THE author suggests that more research is needed at present on modern insecticides. He asks if enough is really done on a matter the results and progress of which are so essential to the basis of our food supply. Fundamental research work on insecticides is almost non-existent; but it could be decisive for the future efficiency of the pest control mechanism. The book is not a handbook in its strict sense, but the attempt to compile a German compendium on modern insecticides. Its disposition is somewhat uneven. For example, there are chapters named "Phenothiazin . . . " alternating with such titles as "Acarizide".

The chief stress in the contents is on chemical constitution, industrial manufacture, historical development and analytical methods. These subjects are discussed in a substantial form, the author himself being very familiar with them as an industrial chemist. The methods of application are described from the point of view of the insecticides, that is, the chapter on a specific insecticide tends to describe the manner in which this insecticide may be applied. On the other hand, the brevity of the book compared with the enormous extent of the whole subject leads to the result that the matter dealt with is limited: the book cannot be complete inasmuch as some minor subjects are omitted. For example, the reviewer missed calcium arsenite as well as the application to warm-blooded animals of systemic insecticides. But this fact is no vital fault of such an introduction; seen as such, the book is quite comprehensive in the subjects discussed.

However, in a very few cases the formulations of the text are not very convincing; for example, such a sentence as "Stored food protection is no simple problem and needs knowledge of the matter as well as responsibility" could have been applied similarly to other insecticidal matters. The chapter on bioassay methods is sufficiently comprehensive for an introduction, while the chapter on insecticide application by aircraft is too short for an English reader. It is a good idea of the author's to go into the subjects of toxicology and biology. Concerning these chapters, it must be borne in mind that the author himself is neither biologist nor toxicologist. Thus some minor points regarding such matters do not show an exactitude comparable to that displayed in his own subject. But the author can be applauded for commending the plant insecticides, since they are less toxic than the synthetic ones. They are especially worthy of recommendation for the control of insects of medical importance or other insects living in inhabited buildings. Considering the shortness of some other chapters, that on historical development is somewhat long. The subject index at the end of the book is very comprehensive and undoubtedly useful.

WD. EICHLER

A SCIENTIFIC ANALYSIS OF FIXATION AND DYEING

Principles of Biological Microtechnique

A Study of Fixation and Dyeing. By Dr. John R. Baker. Pp. 357. (London: Methuen and Co., Ltd.; New York: John Wiley and Sons, Inc., 1958.) 45*s*. net.

WHEN the reviewer began learning the basic techniques of cytology and histology, it was believed that fixing and staining were more an art than a science: with the same material, the same fixative and the same stain, very different results were obtained by good and bad cytologists. For some reason, still mysterious, Unna's methyl green-pyronine always stains nucleic acids properly in Brussels and refuses to do so in many experienced laboratories elsewhere. It is the great merit of Dr. John Baker, who has been deeply impressed by the great work of Ehrlich—to whose memory the book is dedicated—that he has shown that fixing and dyeing are based on sound scientific knowledge: his book contains no practical instructions on how to make a microscopical preparation, but emphasizes "the principle that when we make a microscopical preparation of any sort, we ought to try to understand what we are doing, for otherwise we shall examine an unknown object that has been treated in an unknown way".

Dr. Baker's book is divided into two main parts: fixation and dyeing. In the first chapter, which is an introduction to fixation, the author emphasizes the differences between a fixative and a preservative, a coagulant and a non-coagulant fixative; he then discusses the question of artefacts. The next chapter deals with the visible effects of the reaction of fixatives with proteins (precipitation, flocculation, single clot formation, gel formation, etc.). The chemical changes produced in these reactions are the subject of Chapter 3: coagulants (sublimate, chromium tetroxide, potassium dichromate, acetic acid) are examined in this respect, and the differences between additive and non-additive fixatives are stressed.

In Chapter 4, Dr. Baker examines the reaction of fixatives with tissues and cells, partly on the basis of model experiments made on gelatine - albumin mixtures. Shrinkage and swelling during fixing and embedding in various media are discussed. In Chapters 5 and 6, coagulants (ethanol, picric acid, mercuric chloride, chromium trioxide) and non-coagulants (formaldehyde, osmium tetroxide, potassium dichromate, acetic acid) are considered individually from many points of view (standard concentration for fixation, description, ionization, redox potential, manufacture, introduction as fixative, reactions with proteins, lipids and carbohydrates, rate of penetration, shrinkage or swelling, effects on cell constituents, on dyeing and on the histological picture). Finally, in Chapter 7, twenty-five aqueous and two non-aqueous fixative mixtures are described and discussed.

Chapter 8, an introduction to the chemical composition of dyes, opens Part 2: chromophores and auxochromes are discussed, and pararosaniline, basic fuchsine, leucobases, basic and acid dyes serve as examples. Dyes are classified in Chapter 9 according to their chemical composition, while Chapter 10 deals with the more complex problem of the direct attachment of dyes to tissues: the role of the electric charges on the dye ions and on the objects dyed is especially stressed; the basophil or acidophil character of cellular constituents, apparent isoelectric point of the cell, the effects of washing with water or alcohol, the nature of the fixative mixtures used, etc., are examined in great detail. The subject of the next chapter is, by contrast, the indirect attachment of dyes to tissues (use of mordants, formation of lakes, differentiation, mechanism of Gram staining).

In Chapter 12, Dr. Baker discusses the differential action of dyes: depth of coloration is affected by chemical affinity, density and permeability; nucleic acids and collagen are chosen as the main examples. Metachromasy is examined in the next chapter, the emphasis being placed on Lison's theory. Blood dyes (Ehrlich, Romanowsky, Giemsa) are discussed in Chapter 14, while the two next chapters deal with vital dyes. Finally, dyeing is compared with other processes of colouring in the last chapter: substances which dye cell constituents by dissolving in them are called 'lysochromes' (for example, sudan III in the case of lipids); the principles of silvering and the use of fluorochromes are briefly presented.

The book ends with an appendix, in which the author presents a number of model experiments on fixation and dyeing, as well as a few notes on spelling: for example, he insists on the use of basiphil rather than the usual terms basophil or basophilic. Dr. Baker is probably right there, but he is almost certainly fighting a losing battle: scientists, as a rule, do not care enough about grammatical correctness and etymology to give up words which are in general use and understood by all.

The book is well written and well presented; the many German and French quotations (the latter not always perfectly correct) and the historical approach remind us of the fact that Dr. Baker is a true scholar. There is no doubt that his book will be useful to all those who want to understand what they are doing when they handle cells or tissues with 'classical' histological techniques.

J. BRACHET

MASS SPECTROSCOPY

Nuclear Masses and their Determination

Proceedings of the Conference held in the Max-Planck-Institut für Chemie, Mainz, 10–12 July, 1956. Edited by Prof. H. Hintenberger. Pp. ix+267. (London and New York: Pergamon Press, 1957.) 84*s*. net.

THE conference, the proceedings of which are recorded in this book, was held to mark the sixtieth birthday of Prof. J. Mattauch, of the Max Planck Institute. He has himself contributed much to the growth of mass spectroscopy, which during his life-time has become one of the most precise fields of physics, relative masses being determined in some cases to a few parts in 10^8. This accuracy and the wide number of techniques which are employed make the subject a testing-ground for the methods of several branches of physics. It is in such a situation that a conference can be the greatest stimulus to research, and the proceedings form a current review of the subject in all its aspects.

Since the previous conference on mass spectroscopy in 1951 much of the disagreement between mass values obtained by mass spectroscopes and by nuclear Q-value measurements has been resolved; however, there is still a significant disagreement in some cases, and much of the discussion concerned the possible sources of disparity.

The book opens with an authoritative review of the situation by K. T. Bainbridge, with a good list of references. This is followed by a short account of empirical mass formulae by A. H. Wapstra, and a study of the effects of shell structure on binding energies by U. Cappeller, mainly by a collection of graphs. A paper on the regularities appearing when beta-decay disintegration energies are plotted against neutron number was presented by K. Way, but without theoretical interpretation, and indeed this aspect was sadly lacking at the conference.

The next session comprised the latest mass spectroscopic results, with an excellent account by A. O. Nier on the work at Minneapolis. H. E. Duckworth described some recent determinations at McMaster University. It was unfortunate that L. G. Smith was unable to attend the conference to describe the synchrometer; a table of results was, however, included.

In the following session the measurements of nuclear masses obtained from nuclear reactions were outlined by W. W. Buechner and the techniques described by D. M. van Patter. It was apparent that results from the new large mass spectroscopes under construction will be matched in precision by accurate reaction measurements, over an expanding range of mass numbers. Results extending to titanium-45 were tabulated by P. M. Endt. In the region of heavier elements the method of determining mass differences by the total disintegration energies from beta- and gamma-decay schemes was described by A. C. G. Mitchell; considerably greater accuracy is attainable in suitable cases than by mass spectroscopic means.

The most stimulating session concerned the comparison between nuclear mass-values obtained from Q-values and from mass-spectroscopic doublets, and two very good contributions were given by J. Mattauch and D. M. van Patter. The sources of remaining discrepancies were closely examined, and the need revealed for further doublet measurements to bring the tabulated mass values to a uniform precision. The dependency of the reaction measurements on the calibration standards (such as polonium alpha-particles) requires a careful check to be made, while the work at the Massachusetts Institute of Technology must be augmented and confirmed by other laboratories.

Microwave spectrum measurements were reviewed by S. Geschwind in the following session. Very small amounts of material are necessary for this method, but the difficulty of preparing molecules of suitable symmetry and volatility is considerable and was not fully discussed.

The remaining third of the book is devoted to descriptions of instruments by the leading authorities: Nier (Minnesota), Ewald (Munich), Ogata (Osaka), Bainbridge (Harvard), Duckworth (McMaster), Hintenberger (Mainz) and Goudsmit (Brookhaven). An interesting idea for an electrostatic time-of-flight spectrometer was outlined by M. J. Higatsberger. This section is liberally illustrated with photographs.

The proceedings closed with three short contributions on standards for mass greater than 30 (H. E. Duckworth), the adjustment of mass spectrographs (F. Everling), and the precision of spectral line measurements (A. H. Wapstra).

The book as a whole is very clearly set out, with full lists of references for each paper, while the systematic arrangement of the contents almost makes up for the lack of an index. A summing-up of the proceedings by the editor would have made a valuable addition. With such an array of authors we have in this volume a very rounded account of the experimental side of the subject at the date of the conference. The list reveals, too, how Great Britain, after the brilliant work of Thomson and Aston, abandoned the field to the rest of the world. It is disappointing that no theoretical interpretation was presented of the many regularities and patterns revealed by the considerable precision now available. A method which shows so directly many features of nuclear forces, and can demonstrate so clearly in the packing-fraction curve the energy release by fission and fusion should, one feels, be worthy of more attention.

G. DEARNALEY

THE GRAVITATIONAL FIELD OF THE EARTH

The Earth and Its Gravity Field

By W. A. Heiskanen and Prof. F. A. Vening Meinesz. (McGraw-Hill Series in the Geological Sciences). Pp. x+470. (London: McGraw-Hill Publishing Company, Ltd., 1958.) 97*s*.

THERE is no modern book on the Earth's gravitational field and much of the literature is somewhat inaccessible and confusing; the publication of this book by the two foremost authorities on the subject is therefore most welcome. Throughout they take a broad view and relate the gravity data to the results of other branches of geophysics and to theories of the origin and development of the earth.

The book opens with an account of current views on the interior of the Earth. This is followed by a detailed discussion of the formal theory of the field of an almost spherical body, including terms of the second order of smallness. Nothing very original can be said on this topic, but the discussion is thorough and gives considerable numerical detail. It should be of permanent value as a critical and readable summary of the matter.

Chapter 4 discusses the instruments used for measuring gravity. Most types of pendulum apparatus and gravimeters are mentioned, but the descriptions are somewhat superficial. It would have been interesting, for example, to know how the creep of gravimeter springs has been reduced to the point where it is possible to measure gravity tides with an accuracy of one part in 10^9. A fuller description of the Meinesz pendulum apparatus for use in a submarine would also have been welcome, since the original and only detailed account has become a rare book. A clear diagram is given of the complex system of fused quartz springs employed in the Worden gravimeter, including the arrangements by which the effects of variations in temperature are eliminated. The inventor of the instrument has for many years returned evasive answers to inquiries about this temperature compensation and it is pleasant at last to be told, at any rate in outline, how he achieves his remarkable results.

The next three chapters deal with isostasy. The methods of reducing gravity observations are described in some detail, and much numerical information is given about the degree of compensation found in various parts of the world. There has in the past been much controversy about the reality and generality of isostatic compensation. This controversy seems now to have subsided, and it is clear that the major features of the Earth's crust, the ocean basins, the fold mountains and the great plateaux are, taken as a whole, quite closely compensated, but that there are other features, such as the island arcs and the rift valleys that are not.

The last chapters discuss the causes of these deviations from hydrostatic equilibrium. This discussion is much more speculative than the rest of the book and is concerned with the downbuckling of geosynclines and island arcs and with the hypothesis that the driving forces are due to a system of convection currents. It is always difficult to produce conclusive evidence for or against a major geological theory, and it is perhaps unlikely that the theories of orogenesis, convection currents and polar wandering set out in this book will be generally adopted in the near future. It is, however, of great value to have a systematic account of their views by two authors who have done so much both to provide the data and to understand its meaning.

E. C. Bullard

MECHANICAL VIBRATION

Engineering Vibrations with Applications to Structures and Machinery

By Prof. Lydik S. Jacobsen and Prof. Robert S. Ayre. (McGraw-Hill Series in Mechanical Engineering.) Pp. xii+564. (London: McGraw-Hill Publishing Company, Ltd., 1958.) 77*s*. 6*d*.

THE suppression and control of mechanical vibration have assumed great importance in engineering. One consequence of this is that the number of text-books on the subject is becoming quite large. But, so far as recent books are concerned, this one is unusual in that its authors have something fresh to say and the ability to say it clearly, simply and accurately. The book is meant to be an introductory one for engineers and, as such, it can be measured against the best. In its general layout the book follows the traditional pattern; the reader is led from the analysis of systems having one degree of freedom to systems with two-, then n-degrees of freedom and finally infinite freedom. Within this all-too-familiar framework, however, the book has some important features of its own.

There are two parts. The first of these deals with systems having one degree of freedom and, right from the start, an unusual degree of emphasis is placed on transient oscillation (in addition to steady-state and free vibration). The treatment of this topic is based mainly on phase-plane constructions and it is as lucid and technically entertaining as it is thorough.

A treatment of energy methods is given in this first part of the book, the single degree of freedom corresponding to motion in a single prescribed mode. It contains an elementary account, not only of Rayleigh's principle, but also of the Dunkerley and Southwell variants of it. It is unfortunate that the fundamentals have here to be dealt with in a rather superficial manner. This is more or less dictated by the academic level of the book, and the authors have therefore chosen to buttress the theoretical treatment with several examples. These are quite well chosen though some are rather complicated for the purposes of introduction. A better result might have been obtained by consigning some of the material to the place where it belongs—in the second part of the book.

The chapter on non-linear vibration is unusually readable. This is largely a result of the fact that the authors do not attempt too much. They firmly limit their treatment to two techniques, namely, graphical methods in the phase plane to cover transient and limit-cycle phenomena and the Ritz–Galerkin method for other steady vibration. The combination is shown to be quite satisfactory for the purposes of this book.

It is the reviewer's belief that writers on non-linear vibration seldom pay proper respect to the linear theory of dynamical instability (a subject which is not dealt with to any extent in this book). Thus, on p. 276 there is the statement that " . . . in a study of self-excited vibrations the non-linearities of the terms in the differential equations describing the motions are of paramount importance and . . . a neglect of them is inadmissible". This comment is partially redeemed in the summary of this chapter, but it is a little misleading since it implies that linear analysis is of no value where self-excitation occurs. This is, however, a minor point since the chapter in question is a first-class piece of writing. If the authors could be persuaded to dispel some of the hocus-pocus from other techniques of analysis in the same way, they would place non-linear vibration theory in a better position than it now occupies.

Part 2 of the book relates to linear multi-freedom systems, and the treatment is fairly simple. The authors do not use the Lagrangian equations, there is no discussion of damping, non-linearity is not introduced and emphasis is no longer placed on transient vibration (principal co-ordinates are not mentioned). Even so it cannot be said that this second part of the book is just a mass of familiar theory. For one thing some unusual topics are introduced—for example, the motions of buildings and the vibration of short beams—and for another the theoretical treatment of some topics is unusual. Thus the vibration of a conservative system with n degrees of freedom is the object of a rather unusual form of analysis.

Every chapter has a summary and a set of excellent examples. Many of the latter have answers given. There are also long lists of references which, so far as the reviewer can see, are mostly (though not always) well chosen from the enormous literature on vibration.

Perhaps the best way to describe this book is to say that it serves the same general purposes and can decently be placed on the same shelf as those of Den Hartog and Timoshenko. In other words, this book must be taken seriously. It has a less practical flavour than the former and has, rather, the more mathematical bias of the latter. But it does not duplicate Timoshenko's book by any means.

R. E. D. Bishop

GEOPHYSICAL VOLUMES OF THE HANDBUCH DER PHYSIK

Handbuch der Physik

Herausgegeben von S. Flügge. Band 47 : Geophysik I. Pp. viii+659. 118 D.M. Band 48 : Geophysik II. Pp. viii+1045. 198 D.M. (Berlin : Springer Verlag, 1956 und 1957.)

THE new "Handbuch der Physik" will contain three volumes on geophysics, of which these two are the only ones so far published. Vol. 47 deals with the solid Earth, and Vol. 48 mainly with the atmosphere and oceans. Both volumes consist of a series of separate essays which between them cover most aspects of the physics of the Earth. Vol. 47 contains sixteen articles, and Vol. 48 seventeen ; nearly all are in English and a few in French or German.

Vol. 47 opens with an article by Spencer Jones on the rotation of the Earth. This is largely concerned with the fluctuations in the rate of rotation, the nature of which has become much clearer in recent years owing to the improved time-keeping possible with quartz oscillators and atomic clocks.

Seismology is treated in a group of six papers by J. Coulomb, K. E. Bullen, W. M. Ewing, F. Press and H. Baule. Much of the material is familiar, but the article by Ewing and Press on surface and guided waves gives much new data on a branch of the subject that is advancing rapidly and has been unjustly neglected in the past.

Gravity and isostasy are discussed by G. D. Garland, the structure of the crust by W. M. Ewing, the forces in the crust by A. E. Scheidegger, and the figure of the Earth by K. Jung. Scheidegger's discussion demonstrates how far from solution the major problems of geology still are. In spite of our greatly increased knowledge of what has to be explained, we are still entirely uncertain of the nature of the forces that mould the crust into mountains, island arcs and plateaux.

The longest article in this volume is that by J. T. Wilson, R. D. Russell and R. M. Farquhar on radioactivity and the age of minerals. This is a valuable review of a subject that has not been treated elsewhere in such detail. The use of radioactive methods of age determination should give a new precision and definiteness to the correlation of pre-Cambrian rocks, and a review by three authors who have done so much to make geological sense of the results is most welcome.

The remaining articles are by J. A. Jacobs on the interior of the Earth, by L. Caignard on electric currents in the Earth, and by S. K. Runcorn on the magnetization of rocks and the magnetism of the Earth's body.

Vol. 48 opens with a 154-page article by A. Eliassen and E. Kleinschmidt on dynamic meteorology. Most of this is devoted to general theory and to the properties and formation of vortices. The general circulation and the jet streams are dealt with only briefly.

There are four articles on radiation in the atmosphere, by F. Möller, W. K. Middleton, Z. Sekera and J. Bricard. The space given to this subject seems excessive in relation to the rather brief treatment of some important parts of the dynamical article. The related question of ozone in the atmosphere is treated by H. Paetzold and E. Regener. Other meteorological articles are on sound propagation in air by E. F. Cox, atmospheric electricity by R. Mühleisen, and the physics of clouds by F. H. Ludlam and B. J. Mason. The latter contains a striking photograph of the production of a towering cumulus cloud by seeding.

An article on meteors by A. C. B. Lovell gives a great deal of information that will be new to most readers, including a discussion of data on upper atmospheric winds derived from the motion of meteor trails.

The section on the oceans opens with a general review by H. V. Sverdrup and an article on waves by H. U. Roll. These are followed by four articles on tides. J. Bartels discusses and tabulates the tide-generating forces, and A. Defant, W. Kertz and R. Tomaschek discuss the tides of the oceans, the atmosphere and the solid Earth. Tomaschek's article contains information that is not otherwise easily accessible.

The book ends with an article by S. Sakuma and T. Nagata on physical volcanology. This is concerned mainly with the distortions of the Earth and magnetic changes associated with volcanic eruptions.

Clearly a very great effort has gone into the production of these volumes, and care has been taken to obtain a complete coverage of the subject. The result is a valuable reference work and a convenient means of learning about many matters in which there is widespread interest. Unfortunately the price is so high that few will be able to own the books, and Vol. 47 is so heavy (4½ lb.) as to be unreadable except at a table. E. C. Bullard

PROBLEMS OF HIGH-SPEED FLIGHT

Aerodynamic Components of Aircraft at High Speeds

Edited by A. F. Donovan and H. R. Lawrence. (High Speed Aerodynamics and Jet Propulsion, Vol. 7.) Pp. xiv+845. (Princeton, N.J. : Princeton University Press ; London : Oxford University Press, 1957.) 120*s.* net.

THIS book is Vol. 7 of an important series of twelve volumes which is planned to give a comprehensive account of the problems of high-speed flight. Some of the volumes have already been issued, and of these Vol. 6, on the "General Theory of High Speed Aerodynamics", is of particular interest as the present volume is closely related to it. Whereas Vol. 6 treats the subject of high-speed aerodynamics in a fundamental and general way, the volume under review deals with specific problems such as the determination of the aerodynamic characteristics of particular parts of the aircraft and the interaction of one part on another.

The book is arranged in seven sections, and in the first, Section *A*, R. T. Jones and Doris Cohen of the Ames Aeronautical Laboratory discuss the basic assumptions of wing theory and their validity. The results obtained by the application of various theories to the calculation of air load distributions at subsonic and supersonic speeds are compared and differences analysed. The material is conveniently presented in three chapters ; the first deals with fundamental considerations such as the use of sweepback in the development of wings for high-speed flight, and the second and third consider the prediction of lift and drag characteristics of the wings of various planforms at subsonic and supersonic speeds, respectively. The whole section runs to about 240 pages and gives a comprehensive account of the subject. It would have made an excellent monograph on lifting surface theory if it had been published separately.

Section *B*, by Clinton E. Brown, of Langley Aeronautical Laboratory, deals with the problem of determining the drag, lift, and pitching moment of bodies, and concludes with a short discussion of stability derivatives for bodies of revolution. This section could and should have been more comprehensive; the latest reference cited was published in 1951. Consequently, many important developments of recent years are not discussed, and this chapter can only be regarded as a brief introduction to the subject.

The treatment of interaction problems by C. Ferrari, Politecnico di Torino, in Section *C* is, on the other hand, much more thorough and particular problems are considered in detail. Attention is mainly concentrated on the interference effect the wing has on the tailplane in subsonic and supersonic flow and the mutual interference of wing-fuselage combinations. A chapter of this section is also devoted to the treatment of propeller interference, including the influence of the propeller on the wing, the propeller and propeller-wing combination on the tailplane and the wing on the propeller. The whole section is well illustrated by diagrams giving comparisons between theory and experiment and extends to 270 pages. It ends with a long list of references, but none published later than 1954.

Section *D*, by C. B. Smith, of Pratt and Witney Aircraft Division, is concerned with the aerodynamic design of high-speed propellers, which are assumed to have thin blade sections and to operate at supersonic velocities. The problems are briefly outlined, and on the basis of two-dimensional strip theory the effect of blade section, planform taper and thickness distribution on the performance of the propeller are investigated. Diagrams to illustrate the effects of varying these parameters are given but no experimental results are included for comparison. The author ends his chapter with some brief remarks on practical structural considerations which must also be taken into account in the design of an efficient and reliable propeller.

In Section *E*, J. C. Evvard, of the Lewis Flight Propulsion Laboratory, briefly considers the problems of diffuser and nozzle design. The one-dimensional equations of flow are given in Chapter 1 and are used for describing the general characteristics of diffusion processes on the assumption that marked effects of laminar or turbulent flow separation are absent. It is emphasized that the real problem of subsonic diffuser design is to accomplish diffusion without separation. Methods of predicting laminar and turbulent separations are briefly discussed. Supersonic diffusion processes are considered at length, particular attention being paid to unsteady flow, 'buzz', in supersonic inlets and various causes of loss of pressure recovery. Some of the problems of exit nozzles and jets are briefly outlined in Chapter 2, such as thrust estimation of exit nozzles, the spreading characteristics of jets and the interactions of jets and after-bodies.

Non-steady wing characteristics are fully discussed by I. E. Garrick, of the Langley Aeronautical Laboratory, in Section *F*. He gives an excellent account of the state of knowledge of this subject up to about 1954. The basic theory is treated in some detail, and the exact solutions that have been obtained for two-dimensional flow are outlined. Transient flows are considered and growth of lift functions for subsonic and supersonic flows are given. Various approximate methods of calculating the load distributions on three-dimensional wings are briefly described and discussed. This section is entirely theoretical except for some concluding remarks on experimental methods for determining aerodynamic coefficients for oscillatory motion. A very long list of useful references to relevant theoretical and experimental work is included.

Finally, Section *G*, by C. W. Frick, of the Ames Aeronautical Laboratory, treats "The Experimental Aerodynamics of Wings at Transonic and Supersonic Speeds". This is a most interesting chapter as it compares theory with experiment and discusses the causes of discrepancies, where they exist. An attempt is made to assess the extent to which various theories can be used with confidence to predict air loads on wings at subsonic, transonic and supersonic speeds.

Progress in aeronautics is so rapid nowadays that any book of this kind unless it is printed very quickly is likely to be out of date in some respects when it is issued. The present volume gives the state of knowledge up to about 1954; but, although this is the case, it contains so much valuable information relating to the design of high-speed aircraft that it should be read with interest by all concerned with such work and by aerodynamicists generally.

W. P. Jones

COMPUTERS GALORE

Notes on Analog–Digital Conversion Techniques

Edited by Alfred K. Susskind. (Technology Press Books in Science and Engineering.) Pp. x+415. (Cambridge, Mass.: Technology Press of the Massachusetts Institute of Technology; New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1958.) 80*s*. net.

Computability and Unsolvability

By Prof. Martin Davis. (McGraw-Hill Series in Information Processing and Computers.) Pp. xxv+210. (London: McGraw-Hill Publishing Company, Ltd., 1958.) 58*s*.

Mathematics and Logic for Digital Devices

By Dr. James T. Culbertson. Pp. x+224. (Princeton, N.J.: D. Van Nostrand Company, Inc.; London: D. Van Nostrand Company, Ltd., 1958.) 36*s*.

Logic Machines and Diagrams

By Martin Gardner. Pp. ix+157. (London: McGraw-Hill Publishing Company, Ltd., 1958.) 39*s*.

Electronic Digital Computers

Their Use in Science and Engineering. By Franz L. Alt. (Applied Mathematics and Mechanics, Vol. 4.) Pp. x+336. (New York: Academic Press, Inc.; London: Academic Books, Ltd., 1958.) 10 dollars.

Reading in Linear Programming

By Dr. S. Vajda. Pp. vii+99. (London: Sir Isaac Pitman and Sons, Ltd., 1958.) 20*s*. net.

NOT only are computers themselves becoming so commonplace that more than 1,000 are in operation in the United States alone, but also the literature in the field, once so scant as to prove embarrassing to teachers and students of the art, is turning from a trickle into a deluge.

The present volumes are a fair example of the way in which publishers are attempting to meet the current interest, and they represent between them both analogue and digital computers, their design and their use.

To consider first the analogue field. The book edited by Susskind is devoted to a very small but increasingly important branch of the art: conversion between analogue and digital representations. There are some good things in the volume, particularly the sections on codes and coding and on optical devices, but the book is long for its content and savours too much of the lecture notes from which it was constructed. It is surely not too much to expect proper pagination and an index in a book of this price.

Davis's book is an attempt to explain, in self-contained and simple terms, the theory of computability pioneered by the late A. M. Turing. It is by no means an easy book to read; but the difficulty is inherent in the theory, and the author has done well to make the subject as readable as he has. Applied mathematicians and programmers will be surprised, if they read as far, to find how complex and unintelligible a simple iterative process can become when handled by a pure mathematician and invested with the mysterious cloak of symbolic logic.

The book by Culbertson might well serve as an introduction to Davis's account. It contains some elementary topics such as notational concepts for sums and products, permutations and combinations, probability and number systems. Most of the book, however, is concerned with developing the elementary notions of symbolic logic and particularly of Boolean algebra as applied to switching circuits. The author writes very clearly, and his simple treatment of the synthesis of a reliable switch from unreliable components will come as a relief to those who have attempted to read the late John von Neumann's essay on the same subject. The author provides numerous examples for the reader and cannot blame the reviewer for summing up the book in the words of the author himself when he illustrates an ambiguous sentence (p. 103): "I cannot recommend this book too highly".

On a less-exalted intellectual plane is Martin Gardner's book on logic machines. The author is noted in the United States as a writer on popular scientific topics, and he has succeeded in putting together a fascinating account of the history of these machines. The writing is clear and the illustrations well chosen and interesting. It seems likely, as the author remarks, that digital computers will replace special purpose logical machines, so that this book may well be the definitive epitaph to this subject. The reviewer has only one regret, which is that there are not more details of the mechanisms of the machines.

It is more difficult to give an opinion on Alt's book as the author himself is uncertain as to its purpose, claiming in one place that it is intended as an introduction to the design and operation of computers and in another that it is a book about computer specialists. In fact, the contents suggest a superficial tour through machines and applications rather than a solid account of either. It is very improbable that readers will gain much knowledge of the structure of computers and their components from the first section of the book, which relies exclusively on words and has no illustrative diagrams. In the same way, the section on problem analysis, although it covers a very wide range, proceeds in so highly condensed a manner that it would not be intelligible to a reader who was unacquainted with the topics discussed. The best part of the book is the last section, on computing laboratory organization, where the author's experience makes a valuable and authoritative account.

Last, but by no means least, is the little book by Vajda. This is concerned with problems the solution of which would only be possible, in the large, on a computing machine. The author's previous book dealt with the mathematical basis of linear programming and the present one formulates the systems of equations associated with a wide range of real industrial and sociological problems. Very little mathematical knowledge is required to understand the problems and their solution, and the book will be invaluable as a guide to industrialists and others who want to know how linear programming can be applied in their day-to-day work. It is perhaps unfortunate that the book has not quite the humorous qualities of William's "Compleat Strategyst" but humour in serious scientific books is a matter of taste, and readers may not share the reviewer's enthusiasm for it.

A. D. BOOTH

IMPROPRIETIES RESOLVED

Introduction to Fourier Analysis and Generalised Functions

By Prof. M. J. Lighthill. (Cambridge Monographs on Mechanics and Applied Mathematics.) Pp. viii + 79. (Cambridge: At the University Press, 1958.) 17*s*. 6*d*. net.

IMPROPER functions, such as Dirac's δ-function which is zero everywhere save at the origin but has a non-zero integral over the range $(-\infty, \infty)$, have in the past been used in mathematical physics with much success and some coyness. Schwartz's theory of distributions, the origins of which may possibly lie in Volterra's pioneering work on functionals, has, according to Temple, "replaced the picturesque magic . . . by a self-consistent technique".

Generalized functions are defined as classes of equivalent sequences of ordinary functions, a process not unlike Cantor's mode of defining irrationals by classes of sequences of rationals. A calculus of generalized functions can be constructed without much technical difficulty, derivatives can be defined in a natural way (though products cannot be), and one great advantage is that there is much freedom in interchanging the order of limiting processes. This, as one might expect, simplifies the appropriate Fourier theory: delicate problems on uniqueness and convergence, the delight of the pure mathematician, disappear from a theory in which term-by-term differentiation and unique determination of the coefficients are practically trivial matters. The theory of Fourier transforms is correspondingly simplified, and follows very naturally upon the definition of generalized functions; picturesquely, the Fourier transform of a periodic function is a row of δ-functions. It seems certain that mathematical physics can profit considerably from this new machinery—that the flexibility and directness of symbolic methods can now be exploited more confidently since their account at the bank of mathematical rigour is no longer 'in the red'.

Lighthill's monograph displays in seventy pages the general setting, the theory of generalized functions, of Fourier transforms and Fourier series, with a particularly interesting chapter on the asymptotic estimation of Fourier transforms. The analysis is surprisingly simple, and should be easily intelligible to a reader with a good knowledge of the integral calculus and some small acquaintance with complex variable theory; the Lebesgue integral is not required. But the basic concept of a generalized function, which will be a novelty to many readers, must be thoroughly understood; the novice will do well to read and re-read the second chapter with great care, and he should not take even the simplest of the few exercises for granted. The good honours degree student with an interest in applied mathematics could readily master the book and derive great profit from his mastery. The exposition is concise, lucid and convincing. The dedication reads: "To Paul Dirac, who saw that it must be true, Laurent Schwartz, who proved it, and George Temple, who showed how simple it could be made". To this admirable summary we may add that Lighthill has made a good book of it. T. A. A. BROADBENT

MORLEY COLLEGE

Offspring of the Vic

A History of Morley College. By Denis Richards. Pp. xix+316+7 plates. (London: Routledge and Kegan Paul, Ltd., 1958.) 18*s*. net.

COFFEE and literature seem indissolubly linked—"It helpeth digestion and procureth alacrity", wrote Burton in his "Anatomy of Melancholy"—and from that time to the present-day *Partisan* in Soho, coffee houses have been the penny universities (as Aytoun Ellis described them in his book two years ago) and the clubs that served as therapeutic centres for the intelligentsia. Yet one more illustration of this indissoluble connexion has been provided for us all by Denis Richards.

The Coffee Music Halls Company was itself a blend of Arnoldian idealism (represented by Thomas Hughes and Dean Stanley, both old Rugbeians) and Ruskinism (represented by Emma Cons). Its one and only venture opened its doors on Boxing Day, 1880, in the former Royal Victoria Theatre, re-christened the Royal Victoria Coffee Hall for the purpose. Ballad concerts and lantern lectures lubricated with copious cups of coffee would, it was hoped, redeem the near-bordello character of the area. Purified variety and teetotal surroundings, however, could not keep the venture going, and so Emma Cons obtained the help of *Nature*. Through its columns she appealed to scientists to help her. This was in 1882, and by October 26 in that year she was able to tell readers that every Friday night more than 600 listeners attended lectures by W. L. Carpenter, Norman Lockyer and other scientific men of the day. "Stamps and whistles of impatience" greeted those lecturers whose apparatus broke down.

Rescued a second time by Samual Morley, a hosiery millionaire, and by the enthusiasm for polytechnics, it became Morley College on September 29, 1889. From then until the present day it has been one of the leading adult education colleges of Great Britain. It moved from the Victoria Theatre to 61 Westminster Bridge Road in December 1924, and during the 1930's, under Eva Hubback, most of the distinguished men and women of the decade came to talk. Music was its especial forte. On October 15, 1940, its second lease of life was ended when a 1,000 kgm. high-explosive bomb shattered 61 Westminster Bridge like a pack of cards, and since the Second World War one of its major battles has been to obtain a new building which, thanks to powerful friends, has been successful. The present warden, Mr. Denis Richards, tells the story with grace and insight and his re-creation of the gallant figures who have helped to build Morley College must be welcomed. It is an admirable prelude to the opening of the new buildings by the Queen Mother this autumn, and it will be welcomed by a wide cross-section of the reading public. W. H. G. ARMYTAGE

SECONDARY MODERN SCHOOLS IN BRITAIN

Secondary Modern Schools

An Interim Report. By Prof. H. C. Dent. Pp. xvi+207. (London: Routledge and Kegan Paul, Ltd., 1958.) 15*s*. net.

THIS is an exhilarating book by an assiduous, experienced, shrewd and sympathetic observer of the educational scene. Prof. H. C. Dent surveys the progress in Britain of what is generically called the secondary modern school since its birth, or rather baptism, in 1945, notes with examples the diversity of its evolving variations, reduces the bewildering diversity to the semblance of a pattern, and speculates upon the shape of things to come.

In the course of his description and appraisal of what is, he suggests, implicitly and explicitly, what might be if modern schools were disposed and able to give a general education "not focused primarily on the traditional subjects of the curriculum, but developing out of the interests of children" ("The New Secondary Schools"). This is the theory, indeed it might be called the philosophy, of the modern school conceived as a type. But as Prof. Dent makes abundantly clear, there are all sorts of reasons—pedagogical, psychological and social—why such a school has not emerged as the general type. It offers only one of the many acceptable curricular patterns for schools which are destined to educate so great a diversity of pupils and so large a proportion of the secondary school population.

This interim report on secondary modern schools is an admirable, lucid and just presentation of the schools that are forcing upon us a fundamental reconsideration of the secondary system. We shall not all agree with Prof. Dent's avowedly tentative speculation that the present secondary modern schools will eventually fall into two types: the 'special courses' and 'general certificate of education' schools on one hand, and the 'arts and crafts', 'projects' and 'interest-orientated' schools on the other. But we shall study with attention and respect his reasons for this prognostication.

In my view he attaches more importance than it warrants to the comparatively recent notion of a tripartite division of secondary education, against which the actual developments he so ably describes are in effect a protest. The developments that are going forward in the schools under review should lead us to discard the term 'modern' along with the rest of an outmoded and self-contradictory theory of secondary education. It serves only to confuse the issue and create factitious problems.

When an educationist of Prof. Dent's reputation foresees the emergence of further types of school, the weight of his authority may do something to bring it about. It is to be hoped that he is wrong, since even if the infinite variety of pupils could be fitted into type schools with single-track aims, all 'types' of school could not be made available everywhere to all 'types' of pupil. Rather should we look to the possibility, within a broad conception of education at the secondary stage, of increasing variety within the schools. Instead of multiplying 'types', let us concentrate upon enlarging the capacity and resources of all schools to fit their curricula and methods to the needs of their pupils and thus enable them the better to do their job.

For an eminently readable account of the job the secondary modern schools are actually doing, their difficulties, frustrations and triumphs, we are all indebted to Prof. Dent. H. Raymond King

FUNDAMENTALS OF SYMBOLIC FORM

The Philosophy of Symbolic Forms

By Ernst Cassirer. Vol. 1 : Language. Pp. xiv+328. (1953.) 40*s*. net. Vol. 2 : Mythical Thought. Pp. xviii+269. (1955.) 40*s*. net. Vol. 3 : The Phenomenology of Knowledge. Pp. xvii+501. 68*s*. net. All translated by Ralph Manheim. (New Haven, Conn. : Yale University Press ; London : Oxford University Press, 1957.)

If an attempt is to be made to review what is, in effect, the essence of Ernst Cassirer's life and thought the only way is to treat these three volumes together, notwithstanding the fact that they have emerged from the Yale University Press at various times during the past five years. The translator has done adequately (and Cassirer could be extraordinarily subtle at times), while the historical and interpretative introductions enable Prof. Hendel to act as a welcome guide. The author was probably the last great thinker who could range over almost the whole field of human endeavour, and illumine it at every level. For it was nothing less that was required of anyone who set out to show not only the content but also the significance of symbolic form, whether in language, mythical thought or the phenomenology of knowledge. As specialization spreads more and more over the whole complex of man's activities (with the power that it brings to discovery and invention), so less and less likely does it become that a fair estimate can be made of the degree of mental adjustment which has been taking place in our awareness of those ultimate verities which can only be expressed symbolically. One has but to recollect the rapid advance in mathematics which followed the introduction of rational and consistent notations to see how potent a factor 'form' is : and not only visual form, but mental form, too, as it tends to crystallize out in clarity of exposition.

Vol. 1 (on language) is based upon the phenomenology of linguistic form and discusses the problem of language in the history of philosophy, then as a phase of sensuous and intuitive expression. After this comes the relation of language to conceptual thought, while the sphere of judgment is treated in the last chapter. Throughout Cassirer's work runs the thread of Kant's influence (and of the Neo-Kantian school at Marburg), strong at all times, but especially so when the "Critique of Judgment" is regarded as the interpretation of an epoch. Thus, three problems presented themselves as basic : first, the unity of empirical science, secondly, purpose in Nature, and thirdly, the nature of art. It is not difficult to see how paramount for an understanding of form is a system of communication—language—through which alone the search for natural law and man's own contribution can reach axiological stature.

Vol. 2 (on mythical thought) consists of four parts : myth as a form of thought ; myth as a form of intuition ; myth as a life-form ; and the dielectic of mythical consciousness. (Incidentally, the jacket of this volume carries the title "Mythical Thinking" instead of "Mythical Thought" as on the book itself.)

Of particular interest to the scientist is the discussion of number in relation to the formative period of mathematics. Philolaus (Fragment 11) says that "the nature of number is the cause of recognition, able to give guidance and teaching to every man in what is puzzling and unknown". Translated into psychological terms such as sensation, intuition and feeling, this brings numerical concepts very close to what the Pythagoreans meant by harmony ; and centuries later, Husserl, originally a pupil of the great Weierstrass, arrived at his 'structural forms', and through them at something like a calibration factor for the resolving power of the mind.

Vol. 3 (on the phenomenology of knowledge) is essentially a return, in expanded form, to the author's earlier (1910) conception of substance and function. But the emphasis this time is on structure and articulation, in fact a kind of ultimate analysis of a *Weltanschauung*. Three divisions are clearly discerned, namely, expressive function, representation, and the building up of scientific knowledge. Projected upon this wide intellectual horizon, the earlier volumes, concentrating upon language and myth, are seen at their true value.

To the scientist, the chapters dealing with the object of mathematics, and the system of modern physics will make substantial appeal. In the latter context, it is slightly unfortunate that for Cassirer 'modern physics' necessarily meant the quantum theory of the 1920's—a momentous but somewhat ephemeral phase, and not over-philosophical. What little weakness the translation has comes out here in slight idiomatic mistakes, such as 'ordinal number' for 'atomic number', and 'exponent of refraction' for 'index of refraction'. But a more fundamental matter is the author's strange omission of the *Axiomatik* of Carathéodory (1908), which must have been known to him when discussing the transition from the crude idea of heat to the modern conception of temperature.

Nevertheless, when all is said and done, these three volumes alone (apart altogether from Cassirer's other papers and books) make an outstanding contribution to epistemology and to the human power of abstraction. It is rather as if "The Golden Bough" had been written in philosophical rather than in historical terms. Scientist and humanist are more closely at one when the theme of knowledge is handled on the grand scale, than they are in the domain of specialized studies. Hand in hand they go, in the quest for an ever more perfect symbolic form, at once rigorous and aesthetically rewarding. F. I. G. Rawlins

Van Nostrand's Scientific Encyclopedia

Third edition. Pp. vii+1839. (Princeton, N.J.: D. Van Nostrand Company, Inc.; London: D. Van Nostrand Company, Ltd., 1958.) 220s.

THE third edition of this well-known work is impressively up to date. It is fresh, comprehensive and altogether a masterly production. The amount of material which has been compressed into the volume is really surprising. Five or more pages are given to many subjects, including television, transistors, carbon, computers, guided missiles, satellites, rockets, jet engines, nuclear reactions and reactors. There are also quite comprehensive accounts of subjects such as water, chlorine, perfumes and topical items such as titanium and radio-astronomy. The list could be greatly extended. There are more than 14,000 articles, covering mathematics, engineering, medicine and the physical and biological sciences. The work is very useful for the professional scientist as well as the layman. The topics covered extend even into specialized fields; on the mathematical side, for example, there are accounts of group representations and of Dirichlet integrals and their use in Fourier series.

In compiling a work of this character the decision what to include and what to exclude must be difficult. The reviewer hesitates to suggest additional topics, but must record his surprise at the omission of articles on information theory and on cybernetics. There is practically no mention of man-made fibres, and only two pages are given to quantum theory and one page to the subject of paper. An account of such topics would make the work larger than its present size. Even now, it is a little cumbersome to handle (it weighs 8 lb.). It would seem, therefore, that for future editions it would be a big improvement if the work could be split into two volumes.

L. S. GODDARD

Symposium on Protein Structure

International Union of Pure and Applied Chemistry, Paris Meeting, 1957. Edited by Prof. Albert Neuberger. Pp. 351. (London: Methuen and Co., Ltd.; New York: John Wiley and Sons, Inc., 1958.) 45s. net.

AN account has already been given of the purpose and scope of this Symposium (see *Nature*, 180, 833; 1957). While its object was to assist the Protein Commission of the International Union of Pure and Applied Chemistry in defining 'purity' as applied to protein preparations, its programme was broadened to include many other topics of vital interest to protein chemists at the present time. The emphasis of the papers and discussions, now formally presented in this monograph, is upon the chemical aspects of structure, which include studies of amino-acid sequence and also the more challenging problems of chain-folding and topography of side chains. For certain proteins, all three aspects have been related in some measure to biological activity, especially in the case of the proteolytic enzymes and ribonuclease, and it is, perhaps, this manifold approach which fascinates most. It certainly marks a new phase in the chemistry of biologically active proteins.

Several chapters are devoted to techniques for the separation of proteins, some of which have been almost too successful and have revealed a disturbing micro-heterogeneity. Others emphasize the power of X-rays or of other physical tools to determine absolute structure or variations in it. With one or two exceptions, the contributions are commendably precise and digestible; even a rapid perusal will convince the reader he has been introduced to fields of intense activity and of great reward. The book is a sad reminder, however, that two of its distinguished contributors, Prof. Claude Fromageot and Dr. Rosalind Franklin, are no longer with us.

KENNETH BAILEY

Bacterial Fermentations

By H. A. Barker. (Ciba Lectures in Microbial Biochemistry.) Pp. vii+95. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1957.) 24s. net.

IN 1955, the Ciba Lectures in Microbial Biochemistry were established at the Institute of Microbiology, Rutgers University, and in the spring of each year since then a series of three lectures has been given by an invited speaker. The lectures are afterwards published, and so far three volumes have appeared, of which this is the first. Prof. Barker is well qualified to deal with bacterial fermentations since he and a succession of colleagues have made outstanding contributions in this field for more than twenty years. The author makes no pretence of being exhaustive but rather selects those aspects with which he personally has been most concerned.

The first chapter deals with methane-producing bacteria, some of the most difficult species to isolate and maintain in pure culture. Well-merited attention is given to the physiology of these organisms as well as to the chemistry of their fermentations. Then comes a description of butyric acid and butanol fermentations. This includes the brilliant work on the route of synthesis from ethanol of short-chain fatty acids in *Clostridium kluyveri*, an organism isolated by Barker. The last chapter is concerned with fermentations of nitrogenous compounds—amino-acids, purines and pyrimidines. The influence of Barker permeates every branch of this subject; it is good to have this lucid account, and it is fitting that his ability should have been formally recognized by the naming of a species after him—*Methanosarcina barkerii*.

KENNETH MCQUILLEN

Western Australian Wildflowers

Pp. 24 (22 coloured illustrations). (London: Angus and Robertson, Ltd., 1958.) 5s.

WESTERN AUSTRALIA is one of the world's flower gardens, noteworthy alike for the masses of coloured blossom that greet the eye in spring and for the curious shapes and vividly contrasting hues of so many of the flowers. The cover picture of this booklet presents the illyarrie (*Eucalyptus erythrocorys*) with the curiously contorted crimson operculate buds and golden yellow stamens of the open blooms outlined with the blue-green scimitar leaves and set against a blue Australian sky. Inside, a further twenty-one species are illustrated in colour, ranging from the kangaroo paw (*Anigozanthos manglesii*) strangely clothed in green and crimson wool, to the final picture of the sturt desert pea (*Clianthus formosus*), where a black glossy boss on the standard contrasts vividly with the scarlet petals. Proteaceae are represented by the scarlet banksia (*B. coccinea*) from King George's Sound and the curious sea-urchin (*Hakea laurina*) in which the flowers change gradually from cream to crimson. Other floral gems are the blue *Leschenaultia* (*L. biloba*) and the purple enamelled orchid (*Glossodia brunonis*). Mr. C. A. Gardner, Government botanist for Western Australia, has written brief annotations to the pictures, all of which are good representations of the species they portray. The book should help to stimulate interest in the unique flora of Western Australie. It would make a charming small gift for any plant lover, whether botanist or layman. R. MELVILLE

Amber Spiders in European Collections

By Alexander Petrunkevitch. (Transactions of the Connecticut Academy of Arts and Sciences, Vol. 41, July, 1958.) Pp. 97–400. (New Haven, Conn.: Connecticut Academy of Arts and Sciences; Copenhagen: Ejnar Munksgaard, Ltd., 1958.) 7 dollars.

IN this substantial monograph Prof. Petrunkevitch continues his study of amber spiders with an examination of 230 Baltic specimens, chiefly from collections in France, Germany and Denmark. Forty-seven new species are described, two of them belonging to families, Oxyopidae and Hahniidae, previously unknown in amber. The paper is illustrated by 591 text-figures, and the author gives reasons for preferring line diagrams to photographs: in this respect alone do his methods differ from those of former years. He emphasizes the great importance of labelling every piece of amber containing an arthropod with all the relevant data. The paper includes a list of all known amber spiders, of which 160 species are recognized and which belong to 27 existing and 6 extinct families. T. H. SAVORY

The Chemistry of Borates

Part 1. A Review by Peter H. Kemp. Pp. viii+90. (London: Borax Consolidated, Ltd., 1956.) 12*s*. 6*d*.

THIS monograph is a valuable compilation of chemical and physical data on boron oxides, boric acid, and the borates of the alkali metals and of ammonium, calcium and magnesium. Five pages give the essential background on the element itself, and eight pages deal with the perborates, in which the author believes that there is no adequate evidence for hydrogen peroxide of crystallization.

Data in certain cases include enthalpy, entropy and free energy of formation, specific gravity, solubility, melting points, phase-rule diagrams, crystalline form, X-ray measurements, acidity constants and conductivity. Also, there are useful discussions on complexes with organic compounds and on aqueous solutions of the alkali borates.

The literature seems to have been conscientiously searched up to 1955. The book is well printed and no errors have been detected. A. D. MITCHELL

Spot Tests in Inorganic Analysis

By Prof. Fritz Feigl. Fifth, enlarged and revised English edition. Translated by Prof. Ralph E. Oesper. Pp. xiii+600. (Amsterdam: Elsevier Publishing Company; London: Cleaver-Hume Press, Ltd.; Princeton, N.J.: D. Van Nostrand Company, Inc., 1958.) 65*s*.

THIS, the fifth edition of Prof. Feigl's well-known work, is a companion volume to "Spot Tests in Organic Analysis", and now appears as a book in its own right. Improvements and additions are reflected in an increase of the number of pages from 518 to 600.

The chapter by Prof. P. W. West on "Spot Test Techniques" now contains a description of the ring oven method of Weisz, which has been used for the separation of as many as 14 ionic species in a single drop of solution. Other additions include sections on cyanic, hypohalogenous, perchloric, and hyposulphurous acids, and on free aluminium, lead, zinc, tin, arsenic, molybdenum, vanadium, dicyanogen, and tellurium. Some of the twenty-five additional sections in the chapter dealing with the applications of spot reactions are concerned with, as examples, the detection of arsenic, manganese, nickel, titanium, and chlorine in minerals and rocks, the differentiation of calcite from dolomite, the differentiation of minerals containing barium and strontium, the detection of ammonium salts in filter papers, and the detection of iodine in mineral and sea water.

The book is now established as a standard work: due attention is paid to the chemistry of the tests and to the possibility of interferences. Perhaps, for the benefit of the inexpert, greater emphasis might have been placed on some parts of Chapter 1, for example, by italicizing the sentence on p. 14 which reads, "All experience shows that there are but few absolutely reliable and non-misleading tests". C. O. HARVEY

Abstracts of Papers

Given in the Session on Radiation Chemistry at the All-Union Conference on the Application of Radioactive and Stable Isotopes and Radiation in the National Economy and Science, held in Moscow, March 25–April 2, 1957. Translated from the Russian. Pp. 47. (New York: Consultants Bureau, Inc., 1957.) 10 dollars.

THIS volume contains English translations of abstracts of papers given in the session on radiation chemistry at the conference on the application of radioactive and stable isotopes and radiation in the national economy and science held in Moscow in the spring of 1957. Fifty-five papers are abstracted, about 400 words being devoted to each. Nearly all aspects of radiation chemistry are represented, including the gas phase, aqueous and organic systems, polymers and metal corrosion, and there are several papers on special apparatus and techniques. The translations are excellent. G. PORTER

Symposium on Radiation Chemistry

Academy of Sciences of the USSR, Division of Chemical Science, Moscow, 1955. Edited by Prof. N. A. Bakh. Translated from the Russian. Pp. 223. (New York: Consultants Bureau, Inc., 1956.) 100 dollars.

THIS volume contains full translations of twenty-seven papers presented at the Moscow Symposium on Radiation Chemistry. In her preface Prof. Bakh says: "The symposium as a whole presents a picture of the modern development of various aspects of radiation chemistry in our country".

It is divided into two parts dealing, respectively, with transformations in aqueous systems and with transformations in organic substances. The first part contains investigations of the radiolysis of water, oxidation-reduction processes in inorganic salt solutions, sensitization and protection processes, the action of radiations on colloidal solutions, and a paper on radiolysis of liquid oxygen. The second part includes papers on the radiolytic oxidation of organic compounds, radiation polymerization, the actions of radiations on polymers and mass spectrometry.

The authors include P. I. Dolin, V. I. Veselovsky, the late N. B. Miller, N. A. Bakh, M. A. Proskurnin and V. L. Karpov. The general standard is high, and the topics discussed cover most fields which occupy the minds of radiation chemists at present. The translations are excellent, and, although some time has elapsed since the papers were read, they provide a source of information on Russian work in this field which will be very valuable. Unfortunately, the language barrier has been surmounted only by the introduction of an equally formidable price barrier.

G. PORTER

Sourcebook on Atomic Energy

By Dr. Samuel Glasstone. Second edition. Pp. v+641. (Princeton, N.J.: D. Van Nostrand Company, Inc.; London: D. Van Nostrand Company, Ltd., 1958.) 34*s*.

DR. GLASSTONE'S book, prepared under the direction of the Technical Information Service of the United States Atomic Energy Commission, has been available for eight years and a new edition is therefore timely.

The book seems to have been re-set and is on whiter paper; but it has not lost its excellence as a source of scientific and historical information on nuclear energy. Though much of the text has been retained, it has been brought up to date in several respects: the anti-proton and anti-neutron are included, and more is reported on mesons. Unfortunately, the book just missed the complete declassification of thermonuclear research for the production of nuclear energy, though some of the information which was declassified at the time the book was written has been included. A new and very useful chapter is devoted to reactors; it is of the same high standard as the rest of the book, although the account of the considerable British power achievements seems rather short in comparison with their pioneering importance.

Though it is essentially a physics book, some data on the economics of nuclear energy would be valuable in a next edition.

This new edition stands in the forefront of books of its kind; it provides the 'intelligent layman's guide to nuclear energy'.

E. BRETSCHER

Introduction to Meteorology

By Prof. Sverre Petterssen. Second edition. Pp. ix+327. (London: McGraw-Hill Publishing Company, Ltd., 1958.) 52*s*. 6*d*.

FOR the second edition of a book written seventeen years ago Prof. S. Petterssen has gone to much trouble to provide a complete revision addressed to "students who are considering meteorology as a profession" and also to "students in geography, agriculture, aviation and various industries. . . .".

It is a serious and substantial book surveying weather science from instruments and observations through the basic physical processes to synoptic meteorology and world climate, and yet assuming for the reader a previous knowledge of mathematics and physics at first-year grammar school level. What can be done on this basis is quite remarkable provided that scientific explanation is restricted to the qualitative application of physical principles with an occasional simple formula, and, while it may be doubted whether specialist students of meteorology should begin in this way, there is no doubt of the demand for instructional text-books for the use of those much more numerous students whose interests lie primarily in other fields. The geographers, agriculturists, airmen and the like, who are not only interested in weather science but also may very well need to pass examinations in the subject, may count themselves fortunate in that one of our most eminent professors, now president of the American Meteorological Society, has made the effort to write in simple scientific language yet without any suggestion of writing down.

The book is indeed serious, for the author only twice allows himself a frivolous phrase. It is substantial and up to date although a little surprising in that so little is made of those parts of the subject to which the author has himself contributed so much: three-dimensional dynamical and synoptic meteorology. Possibly what one knows the best seems the least adapted to simple treatment. It is also not impossible to pick a few holes in the fabric. Thus I doubt if a small droplet has a high saturation vapour pressure because it resists the advances of vapour molecules in the air (p. 62); the statement that "normally the mixing ratio will increase from the ground upwards" (p. 84) is of course a slip; that "only a small part" of the solar energy is absorbed in the atmosphere and "the bulk is absorbed at the earth's surface" (p. 88) is an exaggeration of a ratio near 1 : 2; "if the oceans were still there would be little difference between the heat exchanges over oceans and over continents" (p. 95) is a remarkable assertion.

But criticisms of this trivial kind are the only ones which can be levelled against what is a reliable and informative introduction to the study of weather and climate suitable for the non-specialist.

R. C. SUTCLIFFE

The Science of Photography

By Dr. H. Baines. Pp. 319. (London: Fountain Press, 1958.) 38*s*. 6*d*.

ALTHOUGH Dr. H. Baines has written mainly for the non-scientist, any reader having little knowledge of the scientific background of photography will find that this book provides a good introduction to the facts and theories underlying all branches of the subject. The very wide field covered includes chapters on history, optics, the chemistry and physics of the emulsion, its preparation, characteristics and processing, colour photography, scientific and technical applications, etc.

This is a very readable book, which bridges the gap between popular articles, sometimes unreliable, on photographic theory and authoritative works unsuitable for the average photographer. C. O. HARVEY

Introduction to the Theory of Determinants and Matrices

By Edward T. Browne. Pp. xi+270. (Chapel Hill, N.C.: University of North Carolina Press; London: Oxford University Press, 1958.) 60*s*. net.

THIS is a good book, well written and well printed. It covers the theory of matrices, including their applications to algebraic forms; and it covers that theory carefully and thoroughly. A novice reading it may find the going heavy, but the development, though sometimes severe, is logical, clear, and fully stated.

The book is aimed primarily at an American audience and "the text is intended for seniors or first year graduate students". In the author's view there is enough material for two semesters work. It would be a stiff course for the novice.

I have two minor criticisms of the book, both due to personal prejudices of my own: I dislike "it is clear that" and I hate small suffixes. Here argument after argument are admirably presented and then, suddenly, my pleasure is destroyed by a redundant "clearly" or "it is clear that". Finally, the print; the type and lay-out of the text and examples reach a very high standard of mathematical printing, but it has one serious fault. While numerical suffixes are excellent, well set and easy to read, the literal suffixes i and j are microscopic. Whenever I came to these suffixes in a close argument I had to reach for a 'spy-glass' to see which was which.

W. L. FERRAR

Combinatory Logic

Vol. 1. By Prof. Haskell B. Curry, Prof. Robert Feys and Prof. William Craig. (Studies in Logic and the Foundations of Mathematics.) Pp. xvi+417. (Amsterdam: North-Holland Publishing Company, 1958.) 42 guilders.

SOME thirty years ago, a new root stretched out into the very foundations of mathematics, or rather, of mathematical logic. This was the combinatory logic of Schönfinkel and Curry. Its particular task is the study of combinators, which are, in fact, a species of constant operator. In formal logic, one is accustomed to the notion of a variable; what is specific to the new discipline is the recognition that this is a complex concept, amenable to analysis. There is a connexion here (perhaps through Gödel's theorems) with the pre-conditions necessary for the design of antomata, and with Polanyi's heuristic field. There are chapters dealing with the several facets of the method, not excluding its bearing upon semantics and the limitations of language.

Where an essentially deductive element is invoked, especially in the use of quantifiers, the adjective 'illative' is introduced. This is a subtle derivation from the past participle of *inferre*, and is thus slightly apart from inference. The build-up of a formal system is well demonstrated for so simple a case as Euclid's "Elements".

Although the authors modestly disclaim any historical background, it is clear how far theorists have progressed beyond Aristotelian principles: they form but a trivial part of this imposing twentieth-century edifice. A great change in the structure of thought has set in, to bring about these highly specialized analytical techniques.

F. I. G. RAWLINS

Inside the Comprehensive School

A Symposium contributed by Heads of Comprehensive Schools in England and Wales. Collected and Edited by the National Union of Teachers. Pp. 235+12 plates. (London: The Schoolmaster Publishing Co., Ltd., 1958.) 12*s.* 6*d.*

SOME at least of the dust raised by the introduction of the comprehensive schools in England and Wales is beginning to settle. Controversy still continues, but this is, generally speaking, more concerned with education and less with party politics than has all too often been the case. Even so, much of the argument is still tragically uninformed. Critics of the comprehensive school still talk of 'mass production', 'submergence of the individual', 'levelling down', and 'lowering of standards'. This timely little book has little to say by way of special pleading. Instead of argument it invites the reader to 'come and see'.

The seventeen contributors to this symposium are all heads of comprehensive schools. Their immediate concern is to describe how they are dealing with the practical problems of every day, the organization of varied courses, all flexible and interlocked, so that the curriculum can be fitted to the pupil instead of fitting the pupil to the curriculum; the breaking down of large numbers into small units, in which the pupil can feel at home, and where he finds personal understanding and appreciation; the pattern of external and internal examinations, which will provide for the vast majority some opportunity for achievement; the development of the social life of the school community; the problem of staff relations and the delegation of responsibility within the hierarchy; the relation of the school to its neighbourhood.

This is an interim report. There are less than fifty comprehensive schools in the whole of Britain, and only a few of these have had time to reach their full development. It will be another ten years before a final assessment can be made. No two comprehensive schools are exactly alike, but they are one in their conscious endeavour to provide the whole range of secondary education to suit the needs of the whole range of abilities from the candidates for open scholarships to the universities down to the educationally almost subnormal.

The writers are enthusiasts with a clear sense of purpose. They know what they are after and why, and for the reader interested in the 'why?' there is a summing up in the final chapter which may well give the hostile critic second thoughts.

ROBERT W. FENN

Five Years' Work in Librarianship, 1951-1955

Edited for the Library Association by P. H. Sewell. Pp. viii+418. (London: The Library Association, 1958.) 60*s.*

"FIVE Years' Work in Librarianship" succeeds "The Year's Work in Librarianship" which ceased publication with the volume for 1950. Arranged in six sections covering, respectively, national and academic libraries, special libraries, public libraries, young people's libraries and library practice, with a miscellaneous section dealing with librarian co-operation, buildings, bibliography, archives, documentary reproduction, etc., it provides a competent and comprehensive survey of developments and trends in Britain and abroad. Information of special interest to the scientist or technologist is somewhat scattered through the chapters dealing with, for example, national libraries, university and college libraries, technical college libraries, medical libraries, industrial libraries, government libraries, the libraries of learned societies and professional bodies and the commercial and technical departments of public libraries. That even the chapter on library co-operation includes no reference to the lack of progress in the establishment of a national lending or reference library for science and techology is not, however, due to oversight on the part of the compilers, but to the strange lack of interest and support shown in the library world as in that of science and technology. So far as the service of science and technology is concerned, the picture is depressing, but a like survey over the two years following 1955 would provide fair evidence that the period of stagnation is past and that the needs of science and technology are now being faced with more imagination, vision and resource.

A New Method of fractionating High Polymers

We wish to report the results of some exploratory experiments which have been attempted in order to establish a new method for fractionating high polymers.

Zone melting is now recognized as a method of producing materials having a very high degree of purity[1]. Used in the conventional manner, it is found that some impurities are more readily eliminated than others. If, in the case of a high polymer added to a solvent having a suitable melting point, the polymer is eliminated upon zone melting by a process dependent upon some physical parameter which is a function of the degree of polymerization, then this could be used as the basis of a means of fractionation.

In one experiment, a glass tube closed at the base, of 2·2 cm. internal diameter and 30 cm. length, was filled with molten naphthalene. This was first purified by raising the column slowly through a close-fitting heater supplied from a variable voltage source, and the voltage adjusted to give as narrow a molten zone as possible. There was considerable degassing during this process and also purification of the naphthalene, as evidenced by the decreasing opacity of the column after each pass through the heater. After eight passes there was little further change in the purity of the naphthalene contained in the upper portions of the tube.

200 mgm. of polystyrene (*D.C.P.J.*3, Distillers Co., Ltd., Epsom, Surrey. $\overline{M}_n = 80,000$, $\overline{M}_w = 200,000$) was put on the top of the column and taken into solution by arranging the heater and adjusting the heater voltage so that the upper 6 cm. was held in a molten state for 6 hr. This means that initially the polymer was present at 1 per cent concentration at the top of the column. A pronounced opacity, in a region which was formerly transparent, clearly indicated the position of the polymer when the naphthalene solidified. Zone melting was then carried out, using a rate of passage through the heater of 1 in./hr. After one pass it was estimated visually that the polymer had moved 3 cm. down the column, and so was dispersed throughout the upper 9 cm. Eight passes were sufficient to distribute the polymer throughout the whole of the column.

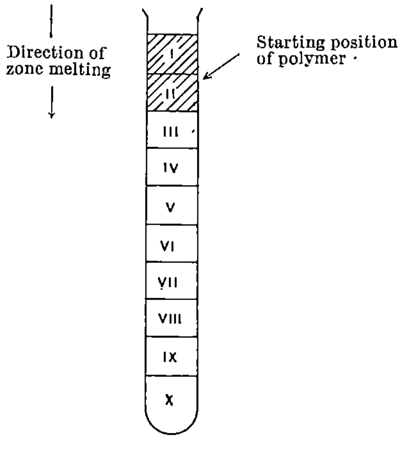

Fig. 1. The column used, showing the initial position of the polystyrene and of fractions recovered

Table 1

Fraction	I	II	III	IV	V	VI	VII	VIII	IX	X
Weight of polystyrene (mgm.)	8·0	7·0	7·5	8·1	6·8	6·4	7·2	6·2	46	106

The polymer was recovered by cutting out the polymer – naphthalene mixture with a flat-faced wood drill so as to produce ten approximately equal portions, and subliming away the naphthalene, which left the polymer in a very fine fibrous state.

The weights of the polymer recovered are given in Table 1, and the positions of the fractions on the column shown in Fig. 1.

The molecular weight and molecular weight distribution of each fraction were assessed qualitatively by turbidimetric titration[2]. In each case 35 ml. of the polystyrene solution, containing 4 mgm./100 ml., was placed in the titration cell, together with 10 ml. of dried methanol. The change in transmission of a light-beam passing through the cell was measured at 1-min. intervals while a further 10 ml. of methanol was added continuously at the constant rate of 0·135 ml./min.

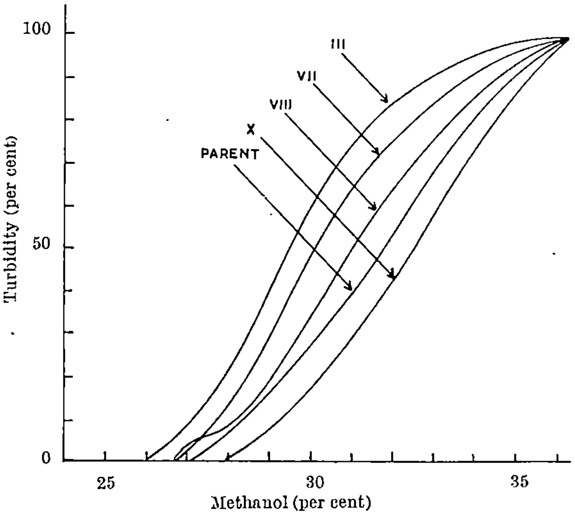

Fig. 2. Turbidimetric titration of the parent polymer and the polystyrene fractions in benzene solution using methanol as precipitant

Fig. 2 shows the change in turbidity of the cell contents with the addition of methanol. The parent material is precipitated over a wide range of solvent – non-solvent ratios, and the materials recovered from the column after zone refining show a much narrower range of precipitation; also the initial precipitation points move in a well-defined sequence.

From this experimental evidence, it can be concluded that the zone melting process can be applied to the fractionation of high polymers. Further investigation of the method is in progress.

Production of Compounds labelled with Carbon-14 from Carbon-14 Dioxide accelerated in an Electric Field

It is well known that hot radioactive carbon-14 and tritium atoms can be used to produce labelled organic compounds often with very high specific activity[1]. This convenient method requires nevertheless a high neutron flux, often yields a cumbersome mixture of labelled compounds and moreover radiation damage frequently produces undesired effects. For these reasons, I have devised a new method in order to avoid such difficulties.

The procedure developed to prepare labelled compounds is based on the acceleration of carbon-14 dioxide by submitting it to a voltage of 500 V. Under such conditions, carbon-14 is able to react with organic compounds or radicals. In the apparatus illustrated in Fig. 1, the two steel electrodes are removable. A thin layer of the organic material to be treated (about 2–10 mgm.) is spread on the cathode. The two bulbs of the cell have ground-glass joints. The cell is connected to a vacuum line and evacuated for an hour to a pressure of 10^{-6} mm. mercury. After carbon-14 dioxide has been admitted at a pressure of $0 \cdot 5 \times 10^{-1}$ mm. mercury, an applied voltage of 500 V. produces a discharge of 100–150 μamp. The cell is then removed and the organic layer diluted in a suitable solvent. After carrier is added, the active sample is purified chemically until it has constant activity. Indeed, part of the activity of the sample is to be attributed to adsorbed carbon-14 dioxide and is consequently labile. After this radiochemical separation, measurements of the radioactivities isolated are carried out by means of a gas-flow counter. By this method, the following simple organic molecules of the aliphatic and aromatic series have been labelled: acetamide, citric acid, succinic acid, benzoic acid and benzoates.

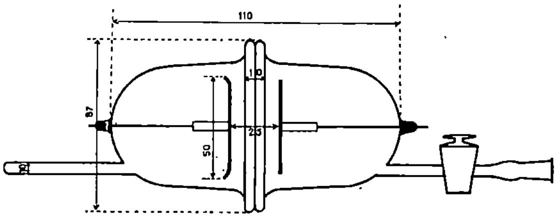

Fig. 1. Diagram of apparatus. Dimensions are in millimetres

In most cases, specific activities are equal to about 0·2 mc./gm. This procedure considerably reduces interference by other adjacent labelled compounds. The specific activities obtained are variable, depending on time of exposure, and increase with the latter. They are also a function of several other factors which are being examined in experiments now in progress. At the same time, the labelling mechanism will be studied. It is hoped that this new labelling technique will be applicable to other radionuclides.

I am indebted to Profs. G. Gueben and J. Govaerts, whose helpful suggestions and encouragement made this work possible. I acknowledge also grants from the Institut Interuniversitaire des Sciences Nucléaires of Belgium.

Hydrogen Overpotential on Germanium Electrodes

Electron transfer reactions at the semiconductor – electrolyte interface are of particular interest because it is not known experimentally whether the reaction kinetics depend upon the bulk electron concentration in the semiconductor. Results of recent measurements of the hydrogen evolution reaction on single crystal germanium electrodes are presented here. The electrode potential (versus the normal hydrogen electrode) was measured under suitable conditions of purity for analysis of the mechanism (Table 1).

Table 1. HYDROGEN OVERPOTENTIAL DATA AT GERMANIUM ELECTRODES (28° C. AND 1 *M* HYDROCHLORIC ACID)

Crystal surface exposed	Bulk electron concentration (cm.$^{-3}$)	Exchange current (amp. cm.$^{-2}$)	$-b$ (mV.)*	$-\Delta\varphi_{i=0}$ (mV.)†
Unknown	4×10^{14}	$1 \cdot 4 \times 10^{-8}$	113	45
Unknown	3×10^{13}	$4 \cdot 7 \times 10^{-6}$	102	1·5
(100)	$\sim 10^{15}$	$(2 \cdot 2 \pm 0 \cdot 3) \times 10^{-8}$	115 ± 12	29 ± 10
(100)	$\sim 10^{12}$	$(2 \cdot 3 \pm 0 \cdot 8) \times 10^{-8}$	109 ± 5	26 ± 6·6
(110)	$\sim 10^{12}$	$(1 \cdot 0 \pm 0 \cdot 2) \times 10^{-9}$	116 ± 2	35 ± 4
(111)	$\sim 10^{12}$	$(1 \cdot 9 \pm 0 \cdot 4) \times 10^{-8}$	148 ± 9	41 ± 20

* $b = 2 \cdot 303\ (\partial\eta/\partial \ln i)$ per decade of current.
† $\Delta\varphi_{i=0}$ is the rest potential of the electrode.

The case where care was taken to ensure that the crystallographic planes were the same on both *n*- and *p*-type germanium (third and fourth entries in Table 1) shows that variation in the bulk semiconductor electron concentration does not produce a corresponding variation in parameters of the hydrogen evolution reaction.

The fact that $\Delta\varphi_{i=0}$ is substantially above zero for most cases shown in Table 1 is interpreted as being due to the dissolution of germanium, that is, the germanium electrode is behaving as a polyelectrode[1]. Such polyelectrode behaviour makes it impossible to obtain the stoichiometric number, ν, for the hydrogen evolution reaction from an analysis of the overpotential – current curve as η goes to zero[2]. However, for one electrode $\Delta\varphi_{i=0}$ is essentially zero and here an analysis of the η versus i curve gives $\nu = 1 \cdot 06$.

Bockris (personal communication) has recently shown that a germanium electrode (supposedly the (110) crystal plane) is covered with a monolayer of adsorbed hydrogen atoms. When this fact is combined with the fact that the Tafel slope is $-2RT/F$ and the stoichiometric number is 1, it can be shown that the only possible simple mechanism for the hydrogen discharge reaction from acid solution is[2]:

$$H_3O^+ + e^- \xrightarrow{\text{fast}} GeH + H_2O$$

$$H_3O^+ + GeH + e^- \xrightarrow{\text{slow}} Ge + H_2 + H_2O$$

(Ge here indicates surface germanium atoms).

This presupposes the mechanism of the hydrogen evolution reaction to be the same on all the germanium crystal surfaces and that the germanium electrode is behaving like a metallic electrode. A more detailed discussion of this work will appear elsewhere.

Macroscopic Surface Structures formed on Boron upon Solidification

THE purpose of this communication is to report some interesting surface structures that formed on a boron surface upon solidification from the melt. Melting was accomplished by electrical resistance heating of rods of polycrystalline boron about 1 mm. in diameter and several centimetres in length in a helium atmosphere. The current through the rod was slowly increased until it melted at the midpoint at about 2,000° C. and separated into two pieces, at which time heating ceased and the melted boron, held on the tips of the remaining pieces, solidified and cooled below red heat within a few seconds.

These rods were prepared by the reduction of boron tribromide by hydrogen on a tiny 0·025-mm. diameter tungsten filament at about 1,200° C. The main impurity in the rods was that of the tungsten core, which amounted to about 0·04 mole per cent. Emission spectrographic analysis indicated small amounts of calcium, iron, copper, magnesium and silicon amounting to a total of 0·02 per cent by weight.

The photomicrograph in Fig. 1 shows what appears to be a hexagonal spiral pit 0·4 mm. across. Several steps can be seen to extend from the outer edge of the spiral to the centre of the hexagon, where they then taper off and finally disappear. The electrical resistance at room temperature between two tungsten probes placed on the surface of the hexagon was about 50×10^6 ohms. Such a high resistance would be expected for boron but not for tungsten boride. A pyramidal pit approximately 0·1 mm. across at the surface and 0·1 mm. deep is shown in Fig. 2. Another structure observed (Fig. 3) was a highly reflective crystal face in the form of a parallelogram, which contained on its surface an equally smooth oval island several microns in height and about 0·2 mm. by 0·3 mm. across.

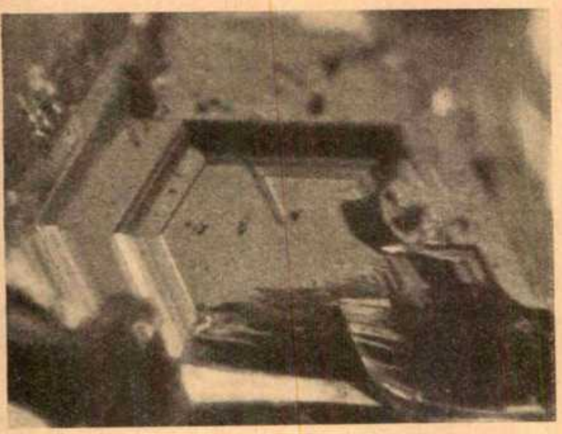

Fig. 1. Hexagonal spiral on boron (0·4 mm. across)

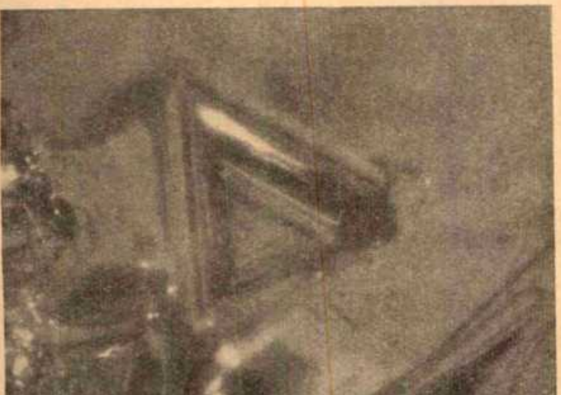

Fig. 2. Pyramidal pit on boron (0·1 mm. across)

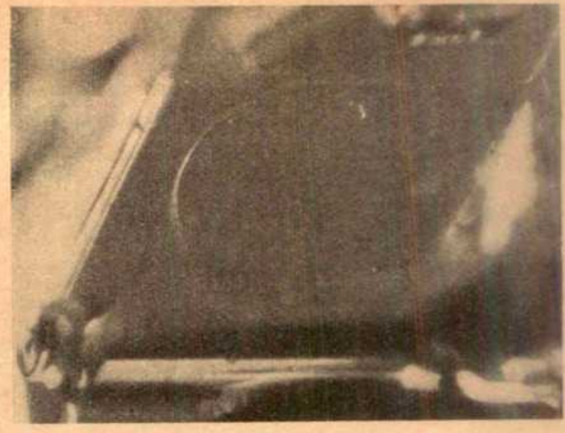

Fig. 3. Oval plateau on boron (0·3 mm. across)

Extractives from Klinki Pine (*Araucaria klinkii* Lauterbach)

THE wood of mature klinki pine trees (*Araucaria klinkii*) frequently contains pink areas running parallel to the grain. When these areas and those closely adjacent to them are moistened with *N* (or stronger) hydrochloric acid, they become vividly green or green-blue, but after 2–3 days fade to a brown colour. Other acids give either a weaker green colour on fresh samples of the wood or show no reaction. Of the other species of this genus the wood of parana pine (*A. angustifolia* O. Kuntze) frequently shows red-coloured bands, but these do not react in a similar manner when acid is applied to the surface of fresh samples. Dry wood of *A. bidwillii* Hook, *A. cunninghamii* Sweet, *A. excelsa* R. Br., and *A. montana* Bronger et Gris gave no response, but a weak reaction was shown by the woods of *A. cookii* R.Br. and *A. bernierii* Buchh.

When the pink wood of klinki pine was extracted in a Soxhlet with hot methanol, a colourless crystalline material (m.p. 235–38°, $\lambda_{max.}$ 256 mμ, yield 0–2·5 per cent) was soon removed, but the components responsible for the green colour reaction were very slowly removed. The yield of the latter varied between 1·3 and 3·4 per cent, with the smallest yield from the most brightly coloured samples, which also contained less crystalline material.

When the non-crystalline fraction, containing six major components (Table 1), was chromatographed on a cellulose column with 6 per cent acetic acid, compounds *B*—*E* were obtained in a total yield of

Table 1. CHARACTERISTICS OF KLINKI PINE EXTRACTIVES

Compound	R_F values in: 6 per cent acetic acid	Methanol–*iso*propyl-ether–water (ref. 2)	Ligroin–*n*-butyl ether–water (ref. 1)	Benzene–ligroin–methanol–water (*c*) (refs. 3 and 4)	Colour or fluorescence	Colour with: Hydrochloric acid	Wiesner's reagent
A	0	0	0	0	brown (*a*)	green-brown	dark lilac
B	streak	0·95	streak	streak	pink (*a*) mauve-opaque (*b*)	green-blue	transient green-blue
C	0·42	0·90	0·28	0·32	green (*b*)	nil	blue
D	0·57	0·88	0·19	0·67	blue-green (*b*)	nil	lilac
E	0·64	0·84	0·19	0·20	mauve (*b*)	nil	intense pink
F	0·72	0·79	—	—	nil	nil	pale pink
Vanillin	0·69	0·94	0·40	0·77			
Syringaldehyde	0·64	0·90	0·13	—			

(*a*) In daylight; (*b*) in ultra-violet light; (*c*) organic phase.

10 per cent of the fraction. After a few days compound *C* became immobile in 6 per cent acetic acid and then turned green with hydrochloric acid. In order to minimize such changes, compounds *B*—*E* were separated on a number of washed No. 3 Whatman papers with 6 per cent acetic acid (or methanol–*iso*propyl-ether–water with compound *B*). As soon as the sheets had dried the bands were cut out, extracted with methanol and examined.

Compound *B* ($\lambda_{\max.}$ (in ethanol) 225, 265 mμ; $\lambda_{\max.}$ (in sodium ethoxide[5]) 248, 289 mμ) decolorized dilute potassium permanganate, and after alkali–nitrobenzene oxidation on a micro-scale yielded vanillin and *p*-hydroxy-benzaldehyde which were identified by comparison with authentic samples in several chromatographic solvents[2]. The green formed in klinki pine appears to be due to compound *B*, and is different from the paler green formed in spruce wood. Pew[6] considers that the blue component of the latter colour is the result of condensation between a substituted coniferyl aldehyde group and a phenylpropane group in the lignin. The absorption maxima of compound *B* in ethanol – 28 per cent hydrochloric acid at −5° C. were 500 and 640 mμ and are higher than those of compounds previously studied[6].

The absorption maxima of compounds *C*—*F* in ethanol were, respectively, 262, 354; 260, 333; 265, 322; 282, 324, 368 mμ. The maxima of compounds *C*—*E* in sodium ethoxide[5] were 268, 418; 260, 405; 250, 376 mμ, and in ethanol and tetramethyl ammonium hydroxide[1] were 225, 286, 422; 225, 285, 405; 225, 243, 290, 386 mμ, respectively. These results suggest that the compounds contain a substituted cinnamaldehyde grouping and a free hydroxyl[7]. This view was further supported by the decolorization of dilute potassium permanganate, reaction with dinitrophenylhydrazine, a strong reaction with phloroglucinol-hydrochloric acid (Wiesner's reagent) and formation of vanillin and *p*-hydroxybenzaldehyde during alkali-nitrobenzene oxidation (see above). It has been shown[8] that only those aromatic compounds containing an aldehyde group in conjunction with a double bond give a purple colour with Wiesner's reagent, but this is the first time a blue colour has been reported as with compound *C*. The absorption maxima of compounds *C*, *D* and *E* in phloroglucinol – 28 per cent hydrochloric acid[9] at 0° C. were 564, 548 and 537 mμ, respectively, and in resorcinol – 28 per cent hydrochloric acid[9] at 0° C. were 642, 580, 566 mμ.

The pink areas are frequently adjacent to decayed regions in klinki pine. The properties of the above compounds suggest that they are lignin degradation products and that they may be the products of microbiological action.

We are grateful to Mr. D. E. Bland for helpful discussions.

Potassium Uptake by Cation-Exchange Resins from Soils and Minerals

THE use of cation-exchange resins for the extraction of soil potassium shows promise of being of value in soil fertility studies[1-4]. Wiklander[1] has discussed the factors which determine the equilibrium distribution of ions between two cation-exchange materials in contact with the same solution. However, the approach to the subject remains empirical because of lack of information on the activity of ions adsorbed on exchanger surfaces. The results with resins in Tables 1 and 2 were obtained by using sufficiently wide ratios of resin to soil or mineral to ensure that practically all the labile potassium was associated with the resin. The potassium analysis was done on the resins (> 60 mesh), which were isolated on a stainless steel sieve (60 mesh) by washing free from finely divided soil or mineral with a jet of distilled water. The washed resin was leached with *N* ammonium acetate and potassium determined in the leachate using an EEL flame-photometer. (Ammonium-exchangeable potassium is defined as that potassium in soil or mineral which is replaced by the ammonium ion during leaching with an excess of neutral *N* ammonium acetate.)

The results in Table 1 on the interaction of 'Amberlite' *IR*-120 resinates with soil slurries show that sodium-resin takes up approximately the amount of potassium that is ammonium exchangeable, while calcium-resin takes up less than the ammonium-exchangeable potassium. A fairly steady state between sodium- and calcium-resins and soil can be attained in 4 days. Considerably more than the

ammonium-exchangeable potassium can be extracted from soil by hydrogen resin. Generally, but not always, the potassium extracted by hydrogen-resin can continue to increase over a month or more of intermittent shaking. Recent work has shown that soil from the long-term experiment at Saxmundham[5] (Suffolk) which has received no potassium fertilizer for 50 years (plot 4) releases significantly more of its non-exchangeable potassium to crops than does soil from the Broadbalk continuous wheat experiment at Rothamsted[6] (plot 11), which has received no potassium fertilizer for more than 100 years. The amounts of potassium extracted by hydrogen resins are in agreement with this finding. Comparing the potassium-treated soils, the Broadbalk soil (plot 13), which has received a higher rate of application for a longer period than the Saxmundham soil (plot 5), released the larger amount of potassium to hydrogen-resin.

Bremner[7] has shown that ammonium ions fixed in vermiculite can be quantitatively extracted by sodium- and hydrogen-resins. In view of the general similarity in the behaviour of inter-layer ammonium and potassium ions, the effects of resinates on some potassium-containing minerals were examined. The results summarized in Table 2 are not all of direct interest in soil studies but certain behaviour patterns are illustrated. It is only with biotite and potassium-saturated vermiculite that sodium- and calcium-resins extract considerably more than the ammonium-exchangeable potassium present in the minerals. Differences in the vigour of the attack by hydrogen-resin on the various minerals are interesting. Whereas the dioctahedral minerals release little of their non-exchangeable potassium to hydrogen-resin, the tri-octahedral minerals suffer considerable loss of potassium. Biotite is completely broken down by hydrogen-resin in about 10 days with the release of all its potassium. Phlogopite and lepidolite release considerable amounts of their potassium to hydrogen-resin in the course of a few days, but the attack progresses more slowly than with biotite. Such minerals as muscovite and 'hydrous mica', which are known to release their potassium to crops with difficulty, are comparatively resistant to hydrogen-resin attack.

Table 2. THE UPTAKE OF POTASSIUM FROM MINERALS BY SODIUM-CALCIUM- AND HYDROGEN-RESINS COMPARED WITH THE AMMONIUM-EXCHANGEABLE POTASSIUM

Mineral (through 100-mesh sieve)	Per cent-potassium	Potassium release (per cent of total in mineral)				
		By leaching with *N* ammonium acetate	By intermittent shaking with 'Amberlite' *IR*-120 (0·2 gm. mineral + 2 gm. resinate + 5 ml. water)			
			Resinate	1 day	4 days	10 days

			Ca	5·1	5·6	5·5
			H	15·0	23·0	43·0
Lepidolite (filings)	6·95	5·6	Na	4·6	5·3	5·3
			Ca	3·6	3·7	4·0
			H	13·0	21·0	37·0
Vermiculite K-saturated	6·19	23·0	Na	49·0	50·0	49·0
			Ca	33·0	35·0	35·0
			H	71·0	75·0	75·0

The hydrogen-resin attack on minerals containing potassium is of a discriminating nature, capable of disclosing the presence of relatively accessible sources of potassium which are not immediately exchangeable. The existing evidence supports the view that hydrogen-resin data may prove to be of value in the assessment of the long-term ability of soils to supply potassium to crops.

Aluminium Interlayers in Soil Clay Minerals, Montmorillonite and Vermiculite

IN the past few years, some workers[1–3] have described the presence in soils of a vermiculite-like clay mineral with a 14 A. basal reflexion, showing a behaviour intermediate between that of vermiculite and chlorite when subjected to the usual procedures for characterization of clay minerals. This was attributed to aluminium in interlayer positions. Tamura[4], of this laboratory, expanded this mineral by removing the interlayer aluminium with sodium citrate followed by saturation with calcium and solvation in glycerol. He thus showed the montmorillonitic nature of this mineral, which is widely distributed in the Holyoke and Wethersfield soils of the north-eastern United States. Considerable quantities of mineral with a stable 14 A. basal spacing occur in Hartford, Charlton and Gloucester soils in Connecticut. Interlayer aluminium may contribute to the low cation-exchange capacity, toxicity of aluminium and fixation of phosphate so commonly encountered in these soils.

After removal of free iron oxides[5] and interlayer aluminium[4] from the clay fractions of these three soils, the 14 A. component behaved like vermiculite. It gave a 14 A. basal spacing on saturation with magnesium and solvation in glycerol which collapsed to 10 A. on saturation with potassium. In contrast, before extraction of aluminium, the spacing did not collapse to 10 A. on saturation with potassium and drying at 100° C. Intensive treatment with sodium citrate for 12 hr. did not result in any further expansion of the 14 A. spacing, thus establishing the identity of this mineral as vermiculite with aluminium interlayers. Thus aluminium interlayers inhibit the expansion of montmorillonite from 14 A. to 18 A. and resist the contraction of both montmorillonite and vermiculite when saturated with potassium and dried at 100° C.

The formation of aluminium interlayers is essentially chloritization of the expanding type 2 : 1 layer silicates in soils. Therefore, the self-explanatory terms 'chloritized montmorillonite' and 'chloritized vermiculite' are proposed, and are used here for the two species which, after the removal of the aluminium interlayers, are characterized as montmorillonite and vermiculite.

Detailed study of the Charlton silt loam profile shows that the mineral component in the fresh and weathered parent rock (Bolton micaceous schist) with 14 A. spacing is a true vermiculite as shown by the contraction of its interlayer space to 10 A., after saturation with potassium. With the greater intensity of weathering near the surface, aluminium becomes more available, and the aluminium interlayers become increasingly stable. In the *A* horizon, 6–9 hr. of extraction with sodium citrate were required to give sharp 10 A. diffraction maxima after saturation with potassium and drying at 100° C., whereas in the B_2 horizon only 3 hr. of extraction effectively removed the interlayer aluminium. In the 14 A. component of the C_1 horizon, a shorter extraction period sufficed. As the weathering of primary minerals proceeds, aluminium becomes more available, and under the mild acid conditions prevailing in this brown podzolic soils region, it is precipitated in the interlayer spaces of the expanding type 2 : 1 layer silicates.

The end product, that is, chloritization, is the complete regradation of chlorite in soils. A continuous chloritized montmorillonite and chloritized vermiculite–chlorite series may exist. Chlorite formation in soil clays is analogous to the laboratory preparation of chlorite from montmorillonite[6].

In clays from some soils of California which are now saline, broad diffraction effects corresponding to spacings higher than 18 A. were observed with the usual glycerol solvation technique. On treating these soil clays with 2 per cent sodium hydroxide[7], diffraction maxima were resolved to 18 A. It was postulated that during some stage of weathering and formation of these montmorillonites, some cations might have been fixed in the interlamellar positions, thus effectively reducing the layer charge on these montmorillonites in this area, thereby resulting in the observed low-angle diffractions. Expansion of bentonite to 22 A. has been obtained (Sawhney, B. L., and Whittig, L. D., unpublished work) by hydrogen saturation followed by suspension in 1 *N* aluminium chloride solution of *p*H 2·7, washing and solvation in glycerol. Similarly, expansion of bentonite to even larger spacings has been achieved by I. Barshad (personal communication).

Thus aluminium may exist in different forms in the two cases: the aluminium interlayers in natural soil clays and the fixation of aluminium under the above experimental conditions. These forms certainly perform different functions in that aluminium interlayers in soil clays resist the expansion of montmorillonite spacings beyond 14 A., whereas aluminium saturation in the laboratory experiment resulted in the greater expansion of the mineral. It is suggested by Tamura[3] that the presence of $Al(OH)_2^+$ ions, and by C. I. Rich (personal communication) the presence of polymerized basic alumina in the interlayer spaces, are responsible for the non-collapse of the chloritized soil clay minerals. At the *p*H of the solution used by me, Al^{3+} or $Al(OH)^{2+}$ ions may be fixed on either side of the montmorillonite layer, thus reducing the overall net negative charge of the layer and consequently increasing the lattice expansion.

Attempts are being made to purify these aluminium-interlayered species from soil clays, and to introduce aluminium into the interlayer spaces of pure montmorillonite and vermiculite.

Ionospheric Measurements made at Halley Bay

IONOSPHERIC measurements at the Royal Society Base at Halley Bay (75° 31′ S. 26° 36′ W. geomagnetic latitude 65° 47′ S.) started on April 1, 1957, and some results for the first year's operation are now available. The Base lies in the zone where the magnetic dip is abnormally small (65°) considering the high latitude and the general ionospheric variations are found to be remarkably regular.

Activity due to the incidence of corpuscular radiation, as shown by the occurrence of high absorption during the winter and equinoctial months, reaches a maximum near 0400 L.M.T. (30° W.) and more than two-thirds of the examples are found between 0100 L.M.T. and 1000 L.M.T. The incidence of high absorption is greatly increased at the equinoxes, as is usual for stations lying within a few hundred miles outside the zone of maximum auroral activity. It is remarkable that the auroral radio-echo index at Halley Bay, which mainly represents auroral activity at higher latitudes, shows a similar diurnal variation but shifted in phase towards the earlier hours. This is unexpected, as the corresponding phase-shift with

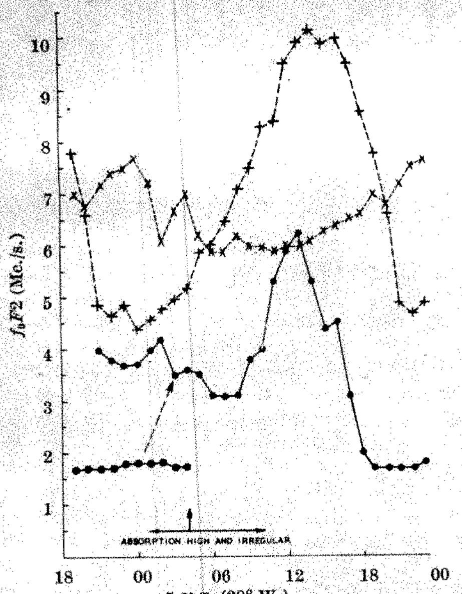

Fig. 1. Monthly median f_0F2 at Halley Bay. ●——●, July (winter); + - - - +, September (equinox); × - - - ×, December (summer)

increase of latitude in the northern hemisphere[1,2] is towards the later hours. The correlations between auroral and ionospheric phenomena appear to be very high, zenith aurora almost always giving high ionospheric absorption accompanied, sometimes, by weak reflexions from heights of about 75–80 km. A thick, group-retarding, auroral E-layer often accompanies auroral activity near the Base.

The detailed results returned to the United Kingdom for the first seven months of operation frequently indicate the presence of consistent recurrent diurnal changes in the F-layer, suggesting that the station is very favourably placed for studying the regular variations of this layer at high latitudes. The ionograms obtained near midnight in winter months show two distinct reflecting structures in the F-region: one which is sequentially continuous (Fig. 1) with the F-layer of the previous day, and the other, which usually first appears with the characteristic shape normally attributed to oblique reflexion from a tilted layer, develops into the F-layer of the subsequent day. Although vestigial reflexions from both structures are usually visible for about eight hours, the change-over from one structure giving the main trace on the ionogram to the other usually occurs in about an hour, near the time marked by the dashed arrow. It is normally complete before the start of the local corpuscular activity, as shown by auroral and blackout phenomena.

The main features of the diurnal variation of the $F2$-layer critical frequency, f_0F2, at Halley Bay are illustrated in Fig. 1. The following points are worth noting: (1) the large diurnal variation of electron density in winter, which is also evident in the total electron content of the layer, having a maximum near noon L.M.T. despite the absence of significant photo-ionization due to solar radiation; (2) the seasonal maxima of electron density in the day found at the equinoxes; these are similar to those found at Port Lockroy (65° S., 64° W.) and Port Stanley (52° S., 58° W.), though in the latter cases the diurnal maximum is reached before instead of after local noon; (3) the small diurnal variation in electron density in summer showing a maximum near midnight L.M.T.; this again is similar, apart from a phase shift, to that found at Port Lockroy; (4) the changes from summer type to winter type diurnal variations near the equinoxes are remarkably sudden, occupying only a few days.

These features suggest, of course, that the diurnal variations of the $F2$-layer near Halley Bay are mainly determined by movements of ionization and not by the recombination processes in the region.

We wish to acknowledge the contributions of Messrs. D. L. M. Cansfield and L. W. Barclay at Halley Bay.

Observations on the Explosion at Ripple Rock

On April 5, 1958, one of the world's largest man-made non-nuclear explosions was fired at Ripple Rock in Seymour Narrows on the west coast of Canada. Briefly, the object of the explosion, which was carried out for the Department of Public Works, Canada, was to remove a twin peaked underwater rock from the centre of a narrow seaway. The method adopted was to sink a 500-ft. shaft on a nearby island and then drive a 2,400-ft. tunnel to points beneath the peaks. Further shafts each 300 ft. high were driven upwards into the rocks and an extensive system of short tunnels was excavated so as to honeycomb the peaks. These tunnels were filled with 1,400 tons of an explosive known as 'Nitramex *2H*' manufactured by the Du Pont Company of Canada. The general arrangement is shown in Fig. 1.

A number of scientific parties observed the explosion and recorded the air blast, the seismic effects, the water waves and the effect on marine life. Among the teams was one from the Atomic Weapons Research Establishment, Foulness, which carried out close-in seismic and air blast measurements, and it is the purpose of this letter to communicate some of the results obtained.

Three types of seismic instruments were used. At the surface of the ground a velocity meter was used which consisted essentially of a mass–spring system in which the damping and natural frequency had been adjusted so that, over the anticipated range of predominant frequencies, the motion of the mass relative to the case was proportional to the velocity of the ground. Cambridge accelerometers were also employed for the surface measurements, these consisting simply of mass-spring systems with a natural frequency, in this case, of 20 c./s. and a damping factor of ½ critical. At underground sites, within the

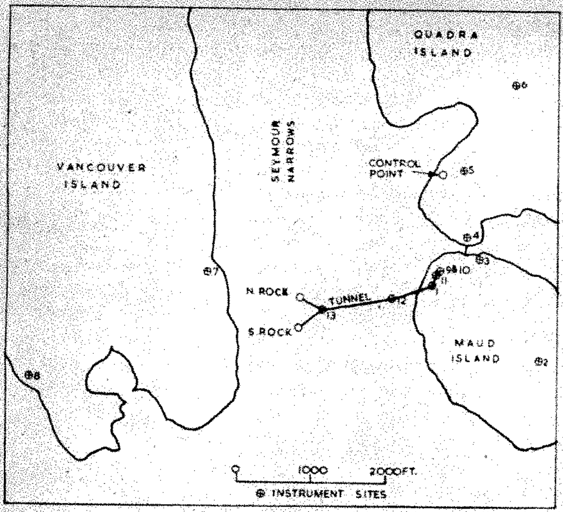

Fig. 1. Ripple Rock project

shaft and along the tunnel, variable-inductance accelerometers were employed. When subjected to acceleration the inductance of the gauges altered and modified the frequency of a local oscillator. The oscillator signals were fed to a central recording site at the top of the mine shaft where they were heterodyned and recorded on magnetic tape. Air blast measurements were obtained by means of mechanical gauges, where the deflexion of a diaphragm under the pressure loading was recorded on a moving film.

All the instrumentation was successful and good results were obtained. Peak accelerations in or out and up or down fitted to an expression of the form:

$$A = 3r^{-2\cdot75} \times 10^8 \ g\text{'s}$$

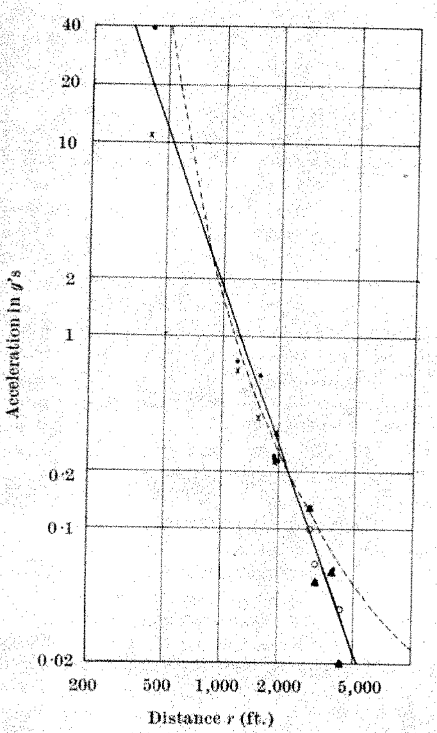

Fig. 2. Acceleration – distance curves. – – –, Prefiring estimate based on Lampson (ref. 1); ——, $3\ r^{-2\cdot75} \times 10^8$; ×, out; ▲, in; ●, up; ○, down

where r is in feet, and agreed well with estimates based on the work of Lampson[1] (Fig. 2). This agreement is remarkable, since Lampson's results were obtained in various types of soils and for the most part with weights of explosive charge of less than 100 lb. Similarly, peak velocities were fitted to an expression :

$$V = 2r^{-1\cdot2} \times 10^3 \text{ ft./sec.}$$

and again agreed well with pre-firing estimates based on unpublished work by the Atomic Weapons Research Establishment with small high-explosive charges. The seismic velocity obtained for the local basalt was 15,000 ft./sec.

An estimate of seismic energy was made from the records and gave 7×10^{16} ergs, about 2×10^{-3} of the available energy calculated on the basis of 4×10^{16} ergs per ton.

The air blast pressure records clearly showed the effect of the 50 feet of rock and water covering the explosive in reducing the peak pressure. The peak pressures of the order of ¼ lb./sq. in. which were recorded at 2,000 ft. were about one-fifteenth of the pressure which would have been expected from the same weight of charge exploded at the surface and were equivalent to the pressure that would have been recorded from only 0·6 tons of T.N.T. fired in this position. The records have a relatively sharp front, although not as sharp as the normal blast wave, but they also have a negative phase (pressure lower than atmospheric) which is much larger in amplitude than that normally encountered in explosive work. This pronounced negative phase will explain the marked Wilson cloud chamber effect which was visible on ciné records of the event.

To assist the long-range seismic measurements undertaken by the Dominion Observatory, Ottawa, an estimate of the time of firing was obtained from the times of arrival of the first seismic pulse in terms of observatory time broadcast for the event by the Canadian Broadcasting Corporation. The resulting firing time was 9.31.02·05 Pacific Standard Time with an estimated accuracy of ± 0·02 sec.

The assistance of the local contractors and constructors and many others is gratefully acknowledged. A great deal of the preliminary work was done by teams from the Suffield Experimental Station of the Defence Research Board of Canada, and to them, and in particular Mr. A. P. R. Lambert, field superintendent, we are deeply indebted. Thanks are also due to the Director of the Atomic Weapons Research Establishment, Aldermaston, and to the Canadian authorities for permission to publish this work.

Presence of 6707 A. Radiation in the Twilight Sky

SINCE August 5, 1958, a patrol spectrograph at Hallett Station in Antarctica has frequently shown the presence of a strong emission line in the region of 6705 A. from the twilight sky. Following a report of this, a grating spectrograph at Invercargill, New

Zealand, was exposed on September 5, 1958, to the radiation coming from the twilight sky between the horizon and 20° altitude, on a bearing of 175° (true). A feeble line at 6707 ± 2 A. was detected on this occasion, and on several subsequent occasions. The use of a minus ultra-violet filter confirmed that the line was in the first-order spectrum. Exposures at varying states of twilight showed that the line was enhanced in twilight at about the same time as the well-known sodium *D*-line enhancement. Hallett station has also observed this twilight enhancement, both morning and evening, from the date of the first detection.

The measured wave-length of this line does not correspond to that of any atomic oxygen or nitrogen line[1], and there is no structure visible that would classify the emission as one of the molecular bands recognized in the spectra of auroræ and airglow[2,3]. The twilight enhancement in a manner similar to that of sodium, occurring at approximately the same time, suggests that the line arises from the $2^2S - 2^2P$ transition in the lithium atom (wave-length 6707·8 A.)[4]. This line is the first member of the principal series of lithium, and thus would be excited resonantly by solar radiation in the same manner as the D-lines of sodium. If this identification is accepted as correct, then the concentration and height of the lithium atoms may be estimated from a preliminary examination of the spectra.

The Invercargill plates show the emission line as a just detectable feature, not strong enough for microphotometry. Until the Hallett spectra are available for precise measurement, accurate estimates of the height and intensity of the lithium line are not, therefore, possible. However, in the middle of August, the lithium emission was observed at Hallett to be of about the same intensity as the total *D*-line emission, and a visual estimate of the density on the Invercargill plates suggests that, in September, the 6707 intensity was of the order of one-tenth the total intensity of the *D*-lines. The oscillator strengths of the lithium 6708 and of sodium 5890 + 5893 are similar[5], and a simple calculation shows that equal intensities of the lithium and sodium lines would result from a lithium concentration 5 per cent that of sodium. The calculation takes into account the Fraunhofer lines in the solar spectrum, and the Rayleigh scattering and ozone absorption in a model atmosphere used previously in colorimetric determinations of the twilight sky[6]. Nicolet[7] gives the total number of sodium atoms above 70 km. as 6×10^9 per cm.^{2}. This suggests that, in August, lithium was present in the upper atmosphere over Hallett to the extent of 3×10^8 atoms per cm.^{2}. The concentration to the south of New Zealand had apparently fallen to 3×10^7 atoms per cm.^{2} by early September. (These concentrations correspond to a total quantity of lithium in the upper atmosphere equal to 20 and 2 kgm. respectively, assuming a uniform distribution over the Earth's surface.)

Calculation of the effect of Rayleigh scattering and ozone absorption on the transmission of radiation through the model atmosphere shows that, after sunset at sea-level, 6708-A. radiation penetrates about 5 km. lower into the atmosphere than does 5893-A. radiation. Applying this correction to measurements of the altitudes above the horizon of the sodium and lithium enhancements observed at different stages of twilight at Hallett, Table 1 gives the estimates of the difference in height between the sodium and lithium layers.

Table 1

Date (1958)		Height of lithium – height of sodium (km.)
August	13	0
	14	-1
	16	-1
	18	-3
	19	-5
	20	-5
	21	-5
	24	-7
	26	-5
	28	-5
September	5	-7

It seems likely that the height of the lithium layer has decreased, relative to the height of the sodium layer, by approximately 0·4 km. per day during the period covered by the observations.

The investigation, of which this is a preliminary report, is part of the research programme of the New Zealand Department of Scientific and Industrial Research. The high-dispersion spectrograph is on loan from the Air Force Cambridge Research Center, through Carter Observatory, Wellington, for the New Zealand International Geophysical Year auroral programme.

Behaviour of the Present Sunspot Cycle

In a communication dealing with the behaviour of the present sunspot cycle, Visser[1] states that the changes in an unspecified ionospheric index are nearly independent of the simultaneous changes in the relative sunspot number, and, in particular, that the rapid increase in the sunspot number in 1957 was not accompanied by a corresponding increase in the ionospheric index.

Visser suggested that the reason for the lack of correlation between the two indices may be that ionospheric phenomena depend on the occurrence of solar eruptions, the incidence of which is not necessarily greatest when sunspots are most numerous. While the radiation emitted during solar eruptions is often known to influence the ionosphere, it is the relatively permanent background radiation which is the principal controlling factor. In view of this, it would be expected that ionospheric indices and sunspot numbers should behave in a broadly similar manner.

Tables have recently been prepared of the monthly mean values of two ionospheric indices, I_E and I_{F2}, which are based respectively on the degree of ionization in the E and $F2$ layers[2]. The unsmoothed values

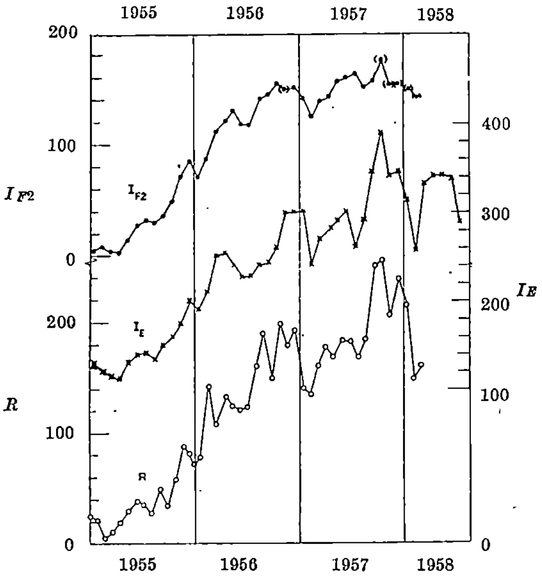

Fig. 1. The behaviour of the present sunspot cycle as indicated by the sunspot number and two ionospheric indices. ●—●—●, ionospheric index, I_{F2} [( ) doubtful value] ; ×—×—×, ionospheric index, I_E ; ○—○—○, rotational mean sunspot number R (after Visser)

of these indices are shown in Fig. 1 for the period January 1955 to date, together with the rotational mean values of the sunspot number taken from Visser's diagram. Both the ionospheric indices and the sunspot numbers vary in a very similar way, and even the smaller irregularities in the trend are sometimes visible in all three curves.

Visser also refers to the secondary oscillations in the sunspot number which occurred during the period 1947–50. These oscillations can also be clearly seen in even the unsmoothed values of the index I_{F2} for this period, and there is some evidence for their existence in the years following the 1938 peak in solar activity[3]. It is important to remember that, although ionospheric ionization is subject to large seasonal changes, there is no significant annual component in the indices I_E and I_{F2}. Hence, the fact that, at the epochs mentioned above, the oscillations in the ionospheric indices have a period of roughly one year cannot be attributed to a residual seasonal component in these indices.

The work described above was carried out as part of the programme of the Radio Research Board and is published by permission of the Director of Radio Research of the Department of Scientific and Industrial Research.

C. M. MINNIS

Radio Research Station,
Ditton Park,
Slough, Bucks.

[3] Minnis, C. M., *J. Atmos. Terr. Phys.*, 7, 310 (1955).

MR. C. M. MINNIS's communication elucidates matters considerably.

The "unspecified ionospheric index" is that determined at De Bilt (daily sums of eight 3-hr. data).

At first I used the f_0F2 data of Slough and Washington[1,2], but since the data from De Bilt coincided fairly well with those of f_0F2 at Washington (ref. 2, Fig. 8) I therefore left the Slough and Washington data and took those of De Bilt, which were directly at my disposal. I must agree now that, for the present purpose, the simple I index of De Bilt does not suffice. As regards the secondary peaks, I find that their period certainly does not have a duration of about one year. I have now completed the investigation from 1863 to date. All sunspot cycles, Nos. 11–19, show the same character with considerable secondary peaks. A broad scattering from 6 to 19 synodic rotations being present, it is evident that there is no question of a regular period. Yet this feature of the sunspots may point to some interesting secondary solar action.

Maxwell Fish-eye treated by Maxwell Equations

THE so-called Maxwell fish-eye[1] is a non-homogeneous lens the index of refraction of which varies according to the relation :

$$n(r) = \frac{2}{1 + (r/R)^2} \tag{1}$$

where R denotes the radius of the sphere, and r the radial distance measured from the centre of the sphere. If a point source is located at the rim of the sphere the lens will focus the rays to another point on the rim at the opposite side. The lens was invented by James Clerk Maxwell in 1860 based upon the method of geometrical optics. It was the year before his enunciation of the electromagnetic theory of light.

In a previous communication[2] the problem of the Luneberg lens was treated rigorously as a boundary-value problem within the framework of the Maxwell equations. It was indicated therein that the same technique can be used to investigate the Maxwell fish-eye. The core of all such radially stratified problems is to resolve two differential equations of the form :

$$\frac{d^2S_n}{dr^2} + \left[k^2\varkappa(r) - \frac{n(n+1)}{r^2}\right]S_n = 0 \tag{2}$$

and

$$\frac{d^2T_n}{dr^2} - \frac{d\varkappa(r)}{\varkappa(r)dr}\frac{dT_n}{dr} + \left[k^2\varkappa(r) - \frac{n(n+1)}{r^2}\right]T_n = 0 \tag{3}$$

where $k = \dfrac{2\pi}{\lambda}$ is the wave-number and $\varkappa(r) = n^2(r)$.

The constant n in these two equations is an integer. The two functions S_n and T_n are associated, respectively, with the transverse electric and the transverse magnetic modes in the analysis of the problem.

For the Maxwell fish-eye, if one substitutes equation (1) into equations (2) and (3) the resultant differential equations can be reduced to the hypergeometric equation by two transformations. Thus, if one denotes :

$$\rho = kr, \text{ and } \rho_0 = kR$$

then by changing the independent variable to ξ defined by :

$$\xi = -\rho^2/\rho_0^2$$

and let:

$$S_n = \xi^{n+1/2}(\xi - 1)^{\mu}U,\ T_n = \xi^{n+1/2}(\xi - 1)^{\mu-1}V$$

where:

$$\mu = \tfrac{1}{2}\left(1 + \sqrt{1 + 4\rho_0^2}\right)$$

it can be shown that the functions U and V satisfy, respectively, the following two equations:

$$\xi(\xi - 1)U'' + [(2\mu + \beta)\xi - \beta]U' + \alpha U = 0 \quad (4)$$

and

$$\xi(\xi - 1)V'' + [(2\mu + \beta)\xi - \beta]V' + (\alpha - \tfrac{1}{2})V = 0 \quad (5)$$

where:

$$\beta = n + \tfrac{3}{2}, \text{ and } \alpha = \beta\mu + \rho_0^2$$

The prime denotes the derivative of the function with respect to ξ.

Equations (4) and (5) are identical, in form, to the hypergeometric equation:

$$\xi(\xi - 1)W'' + [(a + b + 1)\xi - c]W' + abW = 0 \quad (6)$$

By comparing equations (4) and (5) with (6) it is relatively simple to determine the constants a, b, and c in terms of α, β, and μ. For the analysis of the Maxwell fish-eye we only need the hypergeometric function $F(a,b,c,\xi)$, which is regular at $r = 0$.

So far as numerical work is concerned it is, of course, not an easy task. Until such results are available the detailed behaviour of the lens is not known. I wish merely to direct attention to the fact that the Maxwell fish-eye can formally be treated as a boundary-value problem, based upon the equations which Maxwell formulated.

Separation of the Condensing Enzyme of *Aspergillus niger* from Acetyl Coenzyme *A* Deacylase and Citridesmolase and the Effect of Magnesium Ion on the Purified Fraction

THE condensing enzyme found in various tissues has been generally found to require magnesium for its activity. However, an exception was reported by Ramakrishnan and Martin[1], who found that the condensing enzyme of *Aspergillus niger* does not require magnesium and is, on the contrary, inhibited by it. Horecker and Mehler[2] suspected that the presence of citridesmolase as a contaminant might be responsible for this inhibition. Further, the presence of acetyl coenzyme *A* deacylase in cell-free extracts of *A. niger* has been recently detected in this laboratory and the enzyme purified[3]. It will be noted that this enzyme also needs magnesium for optimal activity and that the presence of this enzyme as a contaminant in the condensing enzyme is likely to cause its inhibition by magnesium. I have therefore reinvestigated the problem of the magnesium requirements of the condensing enzyme with reference to the presence of contaminants.

Calcium gel supernatant was prepared from cell-free extracts of *A. niger*, *N.R.C.* 233, according to the method of Ramakrishnan and Martin[4]. The preparation was tested for the condensing enzyme, acetyl coenzyme *A* deacylase and citridesmolase activities with and without magnesium ion. The assay system for these enzymes have already been described[3-5]. The results are given in Table 1.

Table 1. EFFECT OF MAGNESIUM ION ON CONDENSING ENZYME, ACETYL COENZYME *A* DEACYLASE AND CITRIDESMOLASE ACTIVITIES OF CALCIUM GEL SUPERNATANT FRACTION PREPARED FROM *A. niger*

Magnesium ion added	Magnesium ion content (μgm./ml.)	Specific activity of		
		Condensing enzyme	Acetyl coenzyme *A* deacylase	Citridesmolase
–	0·1	30·0	7·0	13·8
+	96·2	18·0	11·8	14·2

The contamination of the condensing enzyme preparation obtained by Ramakrishnan and Martin's method[4] with acetyl coenzyme *A* deacylase and citridesmolase is evident from Table 1. It also appears that magnesium ion inhibits the condensing enzyme and accelerates acetyl coenzyme *A* deacylase activity but does not have any effect on citridesmolase activity. Thus the inhibition by magnesium ion observed in the condensing enzyme preparation might have been due to the presence of acetyl coenzyme *A* deacylase.

The next step, therefore, was to remove these two contaminants from the condensing enzyme and study the effect of magnesium ion on the purified enzyme.

It was possible to obtain the condensing enzyme in a highly purified form as follows.

The methods of preparing cell-free extract of *A. niger*, *N.R.C.* 233 and ammonium sulphate fraction (40–60 per cent) have already been described[4]. The ammonium sulphate fraction was frozen overnight and thawed out and centrifuged. To the clear supernatant was added 0·5 volume of calcium phosphate gel, stirred for 15 min. at 0° C. and centrifuged at 6,000 r.p.m. for 20 min. To the supernatant was added 0·5 volume of alumina gel, stirred for 15 min. at 0° C. and centrifuged.

This procedure was found to yield a highly active condensing enzyme that appears to be completely free from acetyl coenzyme *A* deacylase.

The cell-free extract, the ammonium sulphate fraction, the calcium gel supernatant and the alumina gel supernatant were tested for the activity of the condensing enzyme as well as acetyl coenzyme *A* deacylase with and without magnesium ion.

Table 2. EFFECT OF MAGNESIUM ION ON CONDENSING ENZYME AND ACETYL COENZYME *A* DEACYLASE

Enzyme preparation	Mg++ added	Mg++ content (μgm./ml.)	Specific activity of:	
			Condensing enzyme	Acetyl coenzyme *A* deacylase
(1) Cell-free extract	–	0·2	0·63	1·6
	+	96·2	0·50	2·2
(2) Ammonium sulphate (40–60 per cent saturation) unfrozen	–	0·4	15·0	6·5
	+	96·6	10·5	9·1
(3) Ammonium sulphate fraction (40–60 per cent saturation) frozen and thawed	–	0·4	15·2	0·8
	+	96·6	10·6	1·1
(4) Calcium gel supernatant from 3	–	0·1	30·0	0·5
	+	96·1	18·0	0·7
(5) Alumina gel supernatant from 4	–	0·1	42·0	—
	+	96·1	5·1	—

It can be seen from Table 2 that the condensing enzyme in all the fractions is inhibited by magnesium ion whereas acetyl coenzyme *A* deacylase is activated. It will also be observed that the purified condensing enzyme is still found to be inhibited by magnesium ion. This suggests that the condensing enzyme of *A. niger* may be different from that obtained from other sources in respect of its magnesium requirement.

My thanks are due to Miss Mary Clements, Division of Applied Biology, National Research Council of Canada, for the gift of the strain of *A. niger*, *N.R.C.* 233, and lyophilized *E. coli*.

A Rapid Paper Chromatographic Procedure for the Quantitative Determination of Hydroxyproline

In a recent communication[1], we described a descending paper chromatographic procedure for the quantitative determination of hydroxyproline which required a solvent development of 40 hr. Using horizontal paper chromatography at an elevated temperature, comparable results have been obtained after development for only 4 hr.

Four standard hydroxyproline solutions (*p*H 6·5) containing, respectively, 0·050, 0·075, 0·100 and 0·125 µgm. of amino nitrogen are applied to the paper in 0·5 µl. volumes. The unknown solution is spotted (in 0·5 µl. volumes) to fall within the 0·50–0·125 µgm. range of the standard solutions.

Whatman No. 1 filter paper buffered[2] at *p*H 8·4 and measuring 12 cm. × 17 cm. is used. The origin is 2·5 cm. from one end. A 1·5-cm. tab, folded at right angles to the paper, is inserted into the solvent trough.

The chromatographic chamber and the manner in which the filter paper strip is supported in a horizontal position have been described[3,4].

The developing solvent is prepared at 22° C. in a temperature-controlled room by equilibrating equal volumes of redistilled *m*-cresol (Matheson Co., Inc., practical grade) and *p*H 8·4 buffer (0·067 *M*)[2]. The buffer solution must be within ± 0·1 *p*H to obtain the separation reported here. The solvent-rich phase is placed in the trough and the bottom of the chamber is covered with the buffer-rich phase. The covered chamber is housed in a mechanical convection oven at a temperature of 60° C.

After spotting, the filter paper strip is placed in the chamber and a solvent development of 4 hr. at 60° C. separates hydroxyproline from the other common amino-acids. Following solvent development, the chromatogram is dried for 1 hr. at 60° C. using a mechanical convection oven, dipped in a ninhydrin–isatin solution, and the colour of the hydroxyproline spots is developed by placing the chromatogram in an oven at 60° C. for 15 min. The colour reagent is composed of 270 mgm. of ninhydrin, 130 mgm. of isatin and 2 ml. of triethylamine made up to 100 ml. with water-saturated *n*-butanol. The merits of this hydroxyproline reagent have been discussed previously[5].

The maximum densities of the hydroxyproline spots are measured with a 'Densichron' transmission densitometer (Model 3835 *B*, W. M. Welch Scientific Co., Chicago) using a 1-mm. diameter aperture and no filter. A standard curve is prepared by plotting the logarithm of the known concentrations against the densities. The concentration of hydroxyproline in the unknown solution is then calculated by referring to the standard curve. The standard curves are not reproducible from one paper strip to another, and the standards must be run each time on the same chromatogram with the unknown.

Table 1. ACCURACY AND PRECISION OF THE RAPID HORIZONTAL PAPER CHROMATOGRAPHIC DETERMINATION OF HYDROXYPROLINE

Chromatogram	Calculated concentration (mgm./100 ml.)
1	48·7
2	48·7
3	49·6
4	48·7
5	45·9
6	47·7
7	49·6
8	44·0
9	46·3
Average	47·7
Standard deviation	2·21
Deviation from theoretical value, 46·8 mgm./100 ml. (per cent)	1·9

The accuracy and precision of this rapid paper chromatographic procedure were established by determining the hydroxyproline content of a solution, *p*H 6·5, containing eighteen common amino-acids. The average value of nine chromatograms, 47·7 mgm./100 ml., differed from the theoretical value by 1·9 per cent (Table 1). The standard deviation was 2·21 mgm./100 ml. These values are in good agreement with an error of 0·9 per cent and a standard deviation of 1·41 mgm./100 ml. obtained when the solution was assayed using a descending paper chromatographic procedure[1]. The main advantage of the horizontal procedure is the shortening of the solvent development time from 40 hr. to 4 hr.

Anæmia and Liver Damage in X-Irradiated Animals

A number of authors have found disturbances in various liver functions, damage to the liver in the form of fatty degeneration, and increase in the total liver fats in various mammals after total body irradiation with lethal doses of X-rays. According to Ellinger[1] these changes occur after irradiation with doses exceeding *LD*80, and the mechanism of their origin is not yet quite clear. Severe anæmia after irradiation, and resulting hypoxia of the liver and of other organs, might also occur. We have investigated this possibility, and have found that after total body irradiation with

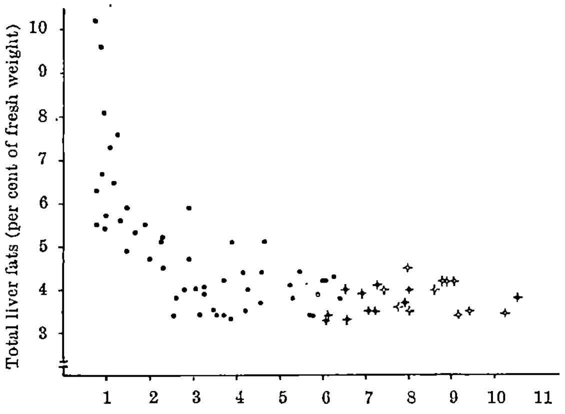

Fig. 1. Relation between the number of red blood cells and the amount of total liver fats in irradiated rats. +, Normal animals; ●, irradiated animals

high doses a striking relation exists between the decrease in red blood cell count and the amount of total liver fats.

Rats of the Wistar strain and white mice of the *H* strain, males and females, were subjected in several experiments to total body X-irradiation (180 kV., 15 m.amp.; 1 mm. aluminium, 0·5 mm. copper; dose-rate, 60 r./min.) with doses of 500–640 r. Food (Larsen diet) and water were given to the animals *ad libitum*. Between the eighth and the twelfth day the irradiated animals and the non-irradiated controls were killed by ether anæsthesia. Red cell counts were made on blood taken from the right heart chamber; in the liver samples, fats were repeatedly extracted with alcohol–ether (3 : 1) and re-extracted with chloroform. The fats were then determined by iodimetric titration after combustion in a solution of potassium dichromate and sulphuric acid[2]. In 22 normal rats the fresh liver tissue contained 3·77 ± 0·345 per cent total fats; for 33 mice the figure was 4·06 ± 0·544 per cent.

The results are summarized in Figs. 1 and 2. From Fig. 1 it is evident that in rats with a red blood cell count less than 2–2·5 million/mm.³, there is, as a rule, an increased amount of fats in the liver. Similarly, for mice (Fig. 2) the liver fats increase when the red cell count drops to less than 4–5 million/mm.³.

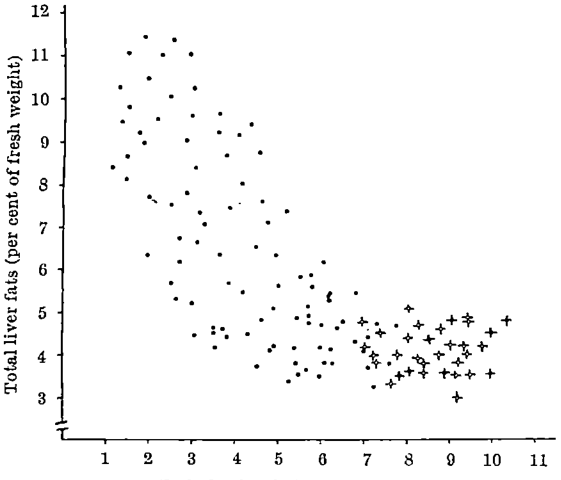

Fig. 2. Relation between the number of red blood cells and the amount of total liver fats in irradiated mice. +, Normal animals; ●, irradiated animals

We may therefore assume that until the critical figure is reached the organism is capable of compensating the deficiency of red blood cells and of hæmoglobin by various mechanisms, such as shifting the dissociation curves of oxyhæmoglobin to the right or increasing the pulse frequency and pulse volume; in severer anæmia the compensatory mechanisms are probably already insufficient. The difference between the critical values for rats and for mice might be related to the findings of Dowdy *et al.*[3], that mice are more sensitive to a decrease of oxygen pressure in the air than rats.

The relation between the drop in the red blood cell count and the rise in the amount of liver fats is not linear in either rats or mice. The partial rectification of the correlation curve of these two values for statistical evaluation is attained by using logarithms of both values. The correlation between the logarithms of the red cell count and the logarithms of the amount of liver fat in rats ($r = 0·87$) is statistically highly significant ($t = 9·3$; $P < 0·0001$). Similar results are obtained for mice.

Clinically, it is known that severe anæmia and the consequent lack of oxygen in the organs causes, among other things, damage to the liver. After irradiation, however, this question has, so far as we know, not been investigated. The correlation is very striking, and certain facts in the literature (for example, that irradiated animals are less resistant to long exposure to reduced oxygen pressure[4]) lead us to assume that severe hypoxia of the tissue after irradiation is fatal to the organism.

Work on this problem is continuing.

Effect of Thyroid Pre-treatment on the Mortality of X-Irradiated Mice

There is difference of opinion with respect to the changes of basal oxygen consumption in animals subjected to X-irradiation and to their significance. Some have observed increased metabolism after irradiation, whereas others have not been able to corroborate these results[1].

We have studied changes of metabolism during adaptation, as a means of ascertaining the activity of metabolic processes. Oxygen consumption is measured immediately after putting the animal into the chamber. As the animal adapts itself to the conditions of the measuring procedure, the changes in oxygen consumption are determined by the condition of the nervous system of the animals. Measuring adaptation consumption of oxygen gives results that are more easily reproducible than serial measurements of the 'basal metabolic' condition, which are more difficult[2,3]. During this work, we have found that animals for which general irradiation is fatal show a reduction of the adaptation consumption of oxygen before their death (L. N., unpublished work). This reduction can be interpreted as failure of the capacity for adaptation of the nervous system, and it can be ameliorated by feeding the animals with thyroid prior to the irradiation. This favourable effect upon the adaptation metabolic capacity of the animals resulted also in higher survival of the irradiated mice.

White male mice of mean weight 30 gm. were fed in groups of 20 with dried thyroid (0·2 gm. gl. thyreoideae siccae per 100 gm. of food). After 20 days, this thyroid pre-treatment was stopped, and five days later the animals were irradiated simultaneously with a control series. They were subjected to this treatment in groups of six, the dose of whole-body X-irradiation being 600 r. (Super Sanax apparatus, 180 kV., 15 m.amp., 1 mm. aluminium, 0·5 mm. copper, target distance 43 cm., 60 r. per min.).

Group 1 (autumn 1957): mortality at 30 days for the control group ($n = 78$) was 71 per cent, while with the treated group ($n = 74$) it was 55 per cent, this difference being statistically significant ($P < 0\cdot05$). Group 2 (spring 1958): mortality at 30 days for the control group ($n = 87$) was 91 per cent, whereas for the treated group ($n = 70$) it was 40 per cent, this difference being highly significant ($P < 0\cdot01$).

The difference in death-rate in the two groups could be observed in the course of the second week, that is, during the period of maximum mortality. As to changes of weight, there was no difference between the experimental group and the control group immediately before irradiation and in the post-irradiation period. Prior to irradiation, as well as on the third and tenth days after irradiation, the adaptation consumption of oxygen was determined for groups of six mice. Fig. 1 gives the statistically significant difference in the average rates of the adaptation consumption of oxygen on the third and tenth days ($P < 0\cdot005$) between the experimental group and the control group.

Such pre-treatment of mice with thyroid, therefore, reduces the post-irradiation mortality. Our results cannot be compared with the experiments of W. W. and F. Smith[4], owing to the different period of feeding which was used. The latter authors showed that when animals are fed with thyroid beginning a week before irradiation and continuing during irradiation, there is a decreased rate of survival of the animals. In our experiments conditions were such as to prevent an absolute increase in consumption of oxygen after irradiation when compared with the pre-irradiation values. We found instead a limited reduction of the adaptation consumption of oxygen. We believe this is due to a relative increase in the activity of the sympathetic nervous system, stimulated by the thyroid treatment.

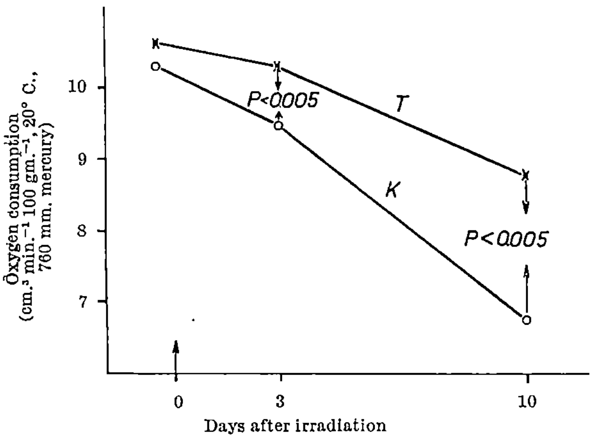

Fig. 1. Changes in oxygen consumption in the adaptation phase (*T*, experimental group; *K*, control group). Ordinates: values of oxygen consumption (cm.³ min.⁻¹ 100 gm.⁻¹, 20° C., 760 mm. mercury dry air). Abscissa: time of examination in days after irradiation

Chemistry of the Rhodopsin Cycle

In 1950, Wald, Durell and St. George[1] found a shift of the absorption maximum in a rhodopsin–glycerin mixture illuminated at − 73° C., and they proposed lumi-rhodopsin as the first intermediate in the rhodopsin cycle. They concluded that lumi-rhodopsin is stable at low temperature, and that when warmed to room temperature in the dark it is converted to a mixture of regenerated rhodopsin and retinene + opsin in roughly equal amounts. We believe[2], however, that the rhodopsin remaining unbleached after low-temperature illumination should not be regarded as having been regenerated from retinene and opsin, but could be recovered directly from lumi-rhodopsin. This communication is a further report of the recovery process.

Cattle rhodopsin solution was prepared as described in our previous paper[2]. After being kept in dry ice-acetone (− 78° C.) or liquid air (− 186° C.) for 5–6 min., rhodopsin solution was illuminated by a fluorescent lamp (2,000 lux, 20 min.), and then immediately raised to room temperature (23° C.) and left in the dark for 1 hr. The absorption spectrum was determined with a spectrophotometer before and after complete bleaching (8,000 lux, 20 min.). The difference spectrum thus obtained was regarded as a measure of the total amount of rhodopsin in the solution.

Fig. 1 shows that the optical density (at 500 mμ) of rhodopsin solution illuminated in dry ice-acetone is 51·4 per cent of that of the non-illuminated solution; in liquid air the corresponding figure is 69·2 per cent. (The solution in dry ice-acetone was orange-red in colour, while that in liquid air was pinkish red.) Furthermore, when the solution illuminated in dry ice-acetone is transferred to liquid air and after 10 min. illuminated again (2,000 lux, 20 min.), the relative amount of rhodopsin is 59·4 per cent, that is, intermediate between the two former values. On the other hand, if the solution is placed in liquid air in the dark after illumination in dry ice-acetone, the relative amount of rhodopsin remains at 51·4 per cent.

The relation between the re-exposure time and the amount of rhodopsin is shown in Table 1. The optical density (at 500 mμ) increases in accordance with the re-exposure time within 30 sec. and then tends to remain constant.

Table 1. OPTICAL DENSITIES (AT 500 Mμ) OF CATTLE RHODOPSIN SOLUTIONS

	Non-illuminated	Illuminated in Liquid air	Illuminated in Dry ice-acetone	After illumination in dry ice-acetone, re-illuminated in liquid air for: 5 sec.	10 sec.	30 sec.	2 min.	10 min.	20 min.
Optical density	0·176	0·114	0·089	0·092	0·093	0·099	0·098	0·103	0·099
Total rhodopsin (per cent)	100	64·8	50·6	52·3	52·8	56·3	55·7	58·5	56·3

Recently, Hubbard and St. George[3] have observed that squid rhodopsin was regenerated from meta-rhodopsin in the light, and they consider that light would promote the interconversion between rhodopsin and meta-rhodopsin, both forming a steady-state mixture. Hubbard and Kropf[4] extended the mechanism to vertebrate rhodopsin and suggested that light is able not only to convert rhodopsin into all-trans lumi- or meta-rhodopsin but also to isomerize all-trans chromophores of lumi- or meta-rhodopsin to a steady-state mixture of stereoisomeric chromophores, all of which are still combined with opsin molecules. The neo-*b* and iso-*a* fraction of this mixture may correspond to rhodopsin and iso-rhodopsin respectively, so that the other isomers (labile fraction) must be regarded as responsible for 'lumi- or meta-rhodopsin'.

Though we carried out no experiments on the isomerization of chromophores, our experimental results suggest that a short-lived intermediate must be produced in any state before rhodopsin will be converted into 'dry ice-acetone illuminated rhodopsin' (lumi-rhodopsin[1]). We assume the existence of 'liquid-air illuminated rhodopsin' which can be clearly distinguished from 'dry ice-acetone illuminated rhodopsin', not only in colour but also in the relative amount of rhodopsin remaining after incubation at room temperature. It is worthy of note that the relative amount of rhodopsin increases when 'dry ice-acetone illuminated rhodopsin' is illuminated in liquid air. In other words, light acts on lumi- or meta-rhodopsin, making it return to 'liquid-air illuminated rhodopsin', that is, the intermediate which is considered to be stable at liquid-air temperatures. We shall call this phenomenon 'photo-recovery'.

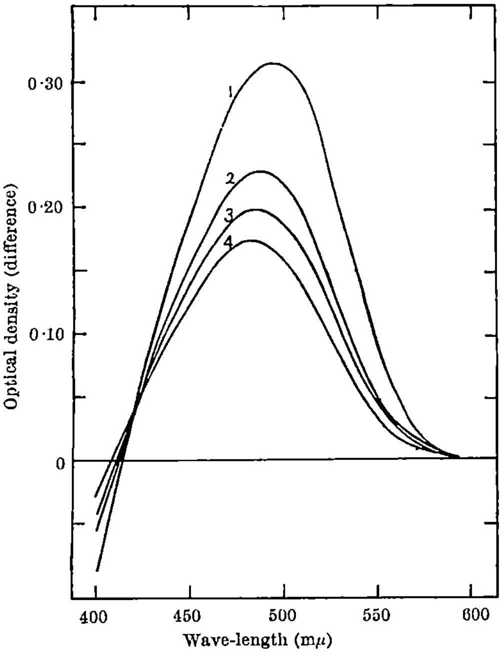

Fig. 1. Difference spectra of cattle rhodopsin solutions. 1, Non-illuminated; 2, illuminated in liquid air; 3, after illumination in dry ice-acetone, re-illuminated in liquid air; 4, illuminated in dry-ice acetone

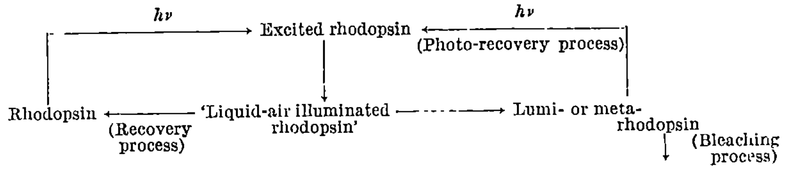
Based on these considerations, we propose a scheme for initial changes in the rhodopsin cycle shown below. When lumi- or meta-rhodopsin absorbs light energy in liquid air, it changes into the excited state (photo-recovery) and then into 'liquid-air illuminated rhodopsin'.



The recovery process and the photo-recovery process may play important parts in rod vision. This will be the subject of our future investigations.

Biochemical Characteristics of Dog Semen

EARLY observations on canine spermatozoa by Leeuwenhoek[1], and Spallanzani[2], although mainly confined to microscopic studies of sperm morphology and motility, included also experiments on various factors affecting sperm activity, and a successful attempt to perform artificial insemination in the bitch. A perusal of the existing literature, however, concerning the chemical composition of dog semen shows that the present knowledge is still very incomplete[3,4]. Moreover, the early analyses of dog semen were carried out mainly with whole ejaculates, although, as already shown by Ivanov[5], dog semen is ejaculated in three fractions, the middle one containing the highest concentration of spermatozoa.

The present study was undertaken in an attempt to extend the information available. The findings are based on an examination of semen from three mixed-breed dogs, using the artificial vagina designed by Harrop[6]. Average figures are quoted in order for the first, second, and third fractions, and the figure for the total ejaculate is in brackets.

The electrolytes determined in dog semen included (m.equiv./l.):

Sodium	164,	149,	154	(133)
Potassium	5·5,	11·5,	7·3	(7·9)
Calcium	1·6,	0·9,	0·4	(0·5)
Magnesium	1·8,	0·8,	0·3	(0·5)
Chloride	154,	169,	160	(150)
Bicarbonate	2·2,	4·2,	2·3	(2·7)

Dog semen also contained (mgm./100 ml.):

Acid-soluble phosphorus	0·7,	29·3,	0·8	(7·4)
Copper	0·26,	1·26,	0·40	(0·51)
Zinc	2·20,	18·40,	7·63	(7·69)
Iron	0·03,	0·06,	0·02	(0·05)
Total reducing substances (expressed as hexose)	15·0,	17·0,	8·0	(20·5)
Fructose	0·47,	2·30,	0·34	(0·56)
Total protein	2,000,	7,000	1,500	(3,000)

It was found that the composition of semen, even if obtained from the same dog, was subject to considerable variation, in particular as regards the levels of sodium and chloride. It was also found that, with a few exceptions, the second, or sperm-rich fraction, appeared to contain the highest concentration of any one constituent.

A noteworthy characteristic of dog semen is the very low level of total reducing substances (20·5 mgm./100 ml.), the majority of which do not disappear on incubation with fermenting yeast, and therefore must not be regarded as fermentable sugar or fructose. However, although dog semen as ejaculated contains no more than a trace of fructose, the fructolytic ability of canine spermatozoa, as expressed in the fructolysis index, was found to be quite appreciable —1·2 mgm. fructose were utilized by 10^9 spermatozoa in 1 hr. at 37° C. Other metabolic studies included measurements of sperm respiration. The oxygen uptake (in the presence of air) was found to be 230 µl. per 10^9 spermatozoa in 1 hr. at 37° C. The dependence of the respiration of canine spermatozoa on the cytochrome system is strongly indicated by the results of spectroscopic analysis. The examination of a suspension of dog spermatozoa in glycerol at the temperature of liquid air revealed the presence of a complete cytochrome system, including the absorption bands of cytochromes *a*, *b*, and *c*.

Effect of Drugs on Emotional Behaviour in Rats

A NUMBER of workers have investigated, in experimental animals, the effects of tranquillizing drugs on learned behaviour motivated by fear. John *et al.*[1] have suggested that reserpine inhibits conditioned avoidance behaviour by interference with learned associations, whereas Weiskrantz[2] believes that reserpine reduces sensory perception. Miller[3] suggested that chlorpromazine reduces fear motivation and that this is independent of its sedative action or of an effect on motor co-ordination.

Since there have been few reports concerning the action of these drugs on unlearned behaviour, some results obtained on emotional behaviour are of interest.

Defecation has frequently been used as a measure of emotional behaviour in the rat and the validity of this measure has been recently reviewed by Broadhurst[4]. Furthermore, emotional defecation is correlated with the acquisition of a conditioned 'anxiety' response[5] and it has been found that chlorpromazine reduces this conditioned defecation[6].

Male rats, fed and watered *ad libitum*, were placed for the first time in an unfamiliar environment, an 'open field'[7], consisting of a small arena 3 ft. 6 in. in diameter. The number of fæcal boluses excreted in 3 min. was used as the index of emotionality[4] or fear, while ambulation was recorded as a measure of sedation. Other types of behaviour such as preening, which may be a 'displacement reaction'[8], and rearing, which was correlated with ambulation, were also noted.

In each experiment the behaviour of treated rats (usually ten per dose) was compared with that of controls and the significance of the results was assessed by *t* tests.

The field was illuminated more brightly at the centre (700 foot candles) than at the periphery (30 foot candles), and this caused the rats to venture into the centre less often than when even illumination (30 foot candles) was employed. This may represent a fear reaction to the light[4].

Chlorpromazine produced a graded and parallel reduction in all types of behaviour (Table 1), but the treated rats did not venture into the centre of the field any more than did the control rats. Reserpine produced similar effects and both drugs caused obvious drowsiness. In contrast to these results, prochlorperazine reduced ambulation, rearing and preening, yet had no significant effect on defecation, and produced very little drowsiness in the doses used.

Table 1. EFFECT OF DRUGS ON EMOTIONAL BEHAVIOUR IN RATS

	Mgm./kgm. subcutaneously	Percentage of control value ± standard error			
		Ambulation	Defecation	Rearing	Preening
Chlorpromazine (1 hr. after injection)	0·5	78 ±30	100 ±20	67 ±16	89±25
	1·0	60 ±15	83 ±22	62 ±16	46±18
	2·0	38 ±13	49 ±15	37 ±14	32±18
Reserpine (18 hr. after injection)	0·5	59 ± 8	91 ±31	63 ±13	140±23
	1·0	16 ± 8	22 ±24	20 ±12	43±17
	2·0	0·7± 7	2·8±22	2·5±12	39±19
Prochlorperazine (1 hr. after injection)	2·5	52 ±13	73 ±25	48 ±22	78±26
	10·0	20 ±13	105 ±25	20 ±20	38±28

In order to investigate the possibility that the reduction in defecation with chlorpromazine and reserpine was due to a peripheral action of the compounds, experiments were carried out to investigate their effects on non-emotional defecation, that is, defecation in rats which had become accustomed to their accommodation (the rats were housed singly in large tins). In these experiments the rats were deprived of food from the time of the injections. Reserpine (2 mgm./kgm.) markedly increased the number of fæcal boluses eliminated, compared with controls ($P < 0·001$), with a maximum effect 2 hr. after the injection. However, fæcal elimination 6–23 hr. after injection was normal ($P > 0·3$). Chlorpromazine (20 mgm./kgm.) increased elimination from 5·6 ± 1·5 (standard error) fæcal boluses per rat (controls) to 9·7 ± 0·9 fæcal boluses per rat (treated animals), throughout 17 hr. following injection. In another experiment 10 mgm./kgm. of chlorpromazine had no effect. When tested in the 'open field' on the second day of the experiment, that is, about 19 hr. after chlorpromazine and 25 hr. after reserpine, the treated rats defecated less ($P < 0\cdot02$) than the controls.

These experiments show that both drugs increased non-emotional defecation. Therefore the reduction in emotional defecation is unlikely to be due to a peripheral constipating effect. Furthermore, the reduction in emotional defecation by reserpine was not due to a decrease in food consumption.

Several other centrally acting drugs have been tested in the 'open field' with the following results.

Benactyzine (4–16 mgm./kgm. subcutaneously) increased ambulation and reduced defecation but the latter effect may be due to a spasmolytic action[9]. Meprobamate, methylpentynol, and pentobarbitone modified behaviour only at doses which caused ataxia, the chief effect being an increase in ambulation. Dexamphetamine resembled lysergic acid diethylamide, the most interesting effect being a reduction in ambulation at the centre of the field with doses (5 and 0·5 mgm./kgm. subcutaneously respectively) having no significant effect on overall ambulation: this suggests potentiation of the stress response to the light.

Since chlorpromazine and reserpine reduced emotional behaviour only at doses which caused sedation, these results suggest that the principal behavioural effect of these drugs in experimental animals is one of sedation, while the reduction in fear-motivated behaviour observed in these experiments and in experiments involving conditioning techniques, is secondary to the sedation.

The results obtained with prochlorperazine support this view since the compound produced less drowsiness than did chlorpromazine in the doses used, and did not reduce defecation. Courvoisier *et al.*[10] also found that prochlorperazine was less active than chlorpromazine in various tests of 'sedation' yet it had a greater cataleptic action. This latter observation could explain why prochlorperazine reduced the motor reactions to the environmental stress, but not the visceral reaction.

It is possible, however, that the measures of fear adopted are insufficiently sensitive to detect effects at small doses.

My thanks are due to Dr. D. R. Maxwell for useful discussion and to Mr. R. B. Hutchins for valuable technical assistance.

Zinc Deficiency induced by Mercury in *Coffea arabica*

A zinc deficiency has been induced in *Coffea arabica* trees in Kenya Colony as a result of spraying with fungicidal formulations containing mercury in organic combination. The symptoms were first observed in October 1957 on coffee trees which had been treated with certain mercurial sprays against coffee berry disease (*Colletotrichum coffeanum* Noack).

The first effects were observed on trees in field trials which had been treated with phenyl mercury acetate, and appeared 4–5 months after the last application of the fungicide. These effects took the form of a severe leaf scorch such as is often associated with the use of phytotoxic materials. Later, other symptoms which affected the growth of the shoots and leaves were observed.

The internodes were abnormally short and some of the youngest leaf pairs were reduced in size, giving the end of the shoot a bunchy, rosetted, appearance. The leaves were often chlorosed in a manner typical of zinc deficiency in this crop, and, in extreme cases, were reduced to the mid-rib. In addition, there were other cases where one pair of leaves was abnormally elongated.

Since it was known that certain of these symptoms are characteristic of zinc deficiency in *Coffea arabica*. leaves from affected trees and from adjacent unsprayed and unaffected controls were analysed spectrographically for zinc content. The results of these preliminary analyses are given in Table 1.

Table 1

	Zinc content (p.p.m.)
Affected leaves (taken from trees which had received six applications of phenyl mercury acetate)	3·6
Control leaves (unsprayed)	14·0

Comparative analyses were afterwards made of first, second, third and fourth leaf-pair samples, counting from the apex of the shoot, collected from both sprayed and unsprayed trees. The figures obtained from these analyses are given in Table 2.

Table 2

	Leaves from sprayed shoots (p.p.m. zinc)	Leaves from unsprayed control (p.p.m. zinc)
First leaf pair	13	31
Second leaf pair	14	20
Third leaf pair	9	19
Fourth leaf pair	8	7

The phenyl mercury acetate sprays are, therefore, associated with a greatly reduced zinc content at the distal ends of the shoots.

The difference in the zinc content of both the controls and the sprayed material shown in Tables 1 and 2 above is attributed to the time of sampling. For the analyses shown in Table 1, material was collected towards the end of the dry season, whereas the material which yielded the results shown in Table 2 was collected eight weeks later, after a period of rain.

Formulations containing mercury in soluble form, such as phenyl mercury acetate, have been observed to cause more severe symptoms than, for example, the relatively insoluble phenyl-mercury-8-hydroxyquinoline.

It is also evident from observations in the field that shoots which are most exposed to the direct rays of the sun suffer more severely. Trees under shade trees show far less severe symptoms.

Similar symptom effects to those described above have been observed by one of us on *Coffea arabica* in the Kivu District of the Belgian Congo following spraying with a formulation containing arsenic. It would thus appear that the effect is not confined to sprays containing mercury. The mechanism of this effect, together with other aspects of the phenomenon, are being studied.

Labelling of Cells in Thoracic Duct Lymph of the Guinea Pig after Tritiated Thymidine

Since tritium gives precise localization in radioautographs[1], and in view of the fact that thymidine is generally believed to be specifically incorporated into deoxyribonucleic acid[2], tritiated thymidine has been employed in recent years to an increasing extent for the study of cellular proliferation.

The studies now reported have been conducted on a series of 22 male guinea pigs, of mixed strain, weighing approximately 400 gm. each. Tritiated thymidine with specific activity of either 0·36 or 1·9 curies/mM. was given in doses of 1 μc. per gm. body-weight, and thoracic duct lymph and blood were studied in smear preparations at various periods afterwards. Suspensions and sections were also prepared of thymus, cervical and mesenteric lymph nodes, spleen and bone marrow. Coated radioautographs were prepared by the method of Belanger and Leblond[3].

Labelled lymphocytes began to appear in lymph during the first hour after the administration of tritiated thymidine, and were thereafter present for several days. To begin with, labelled large lymphocytes are mainly in evidence, though some medium lymphocytes are also seen. Gradually, the size distribution of the labelled cells changes, so that in one experiment the size distribution during the first hour was 47 : 7 : 0 (that is, 47 large, 7 medium and 0 small lymphocytes), in the second hour 48 : 20 : 0, in the third hour 57 : 35 : 4 and in the fourth 75 : 64 : 20. Labelled small lymphocytes began to appear during the third hour and then gradually increased. In the lymph of another animal, obtained at 14 hr. after thymidine, the size distribution among the labelled cells was 47 : 75 : 54, and in lymph collected after 25 hr. it was 33 : 65 : 94. After a single injection of thymidine, a steady stream of labelled lymphocytes, ranging from 2·0 to 7·0 per cent of the total thoracic duct cells, enters the blood over several days. These findings, which differ from those of Gowans[4] in the rat, suggest the continuous liberation of cells from a precursor pool. Labelled small lymphocytes were also found in the blood by the seventh hour, and in view of the work of Bond *et al.*[5], are presumably cells which have entered the blood after labelling in the lymphoid tissues.

Examination of the lymphoid tissues shows active synthesis of deoxyribonucleic acid from the outset, especially in the germinal centres. Though accurate quantitation is not yet possible, it seems clear that there is extensive new formation of lymphocytes; and that a large number of the small lymphocytes i thoracic duct lymph must be newly formed cells The results do not support the concept either o massive re-utilization[6] or large-scale recirculation[7].

Some Structural Characteristics of Myelinated Nerve Fibres

In a previous communication[1] observations were made concerning some errors attendant on methods which have been used in the quantitative examination of myelinated nerve fibres.

A technique demonstrated[2] to the Anatomical Society of Great Britain and Ireland on February 28 has been used to investigate the size relation of the axon and its myelin sheath[3]. During examination of the sural nerve and the nerve to the medial head of the gastrocnemius muscle of the rabbit some points of general interest not previously published have emerged.

5-μ transverse sections of fresh nerve were examined using a polarizing microscope, and measurements of axonal and external diameter made.

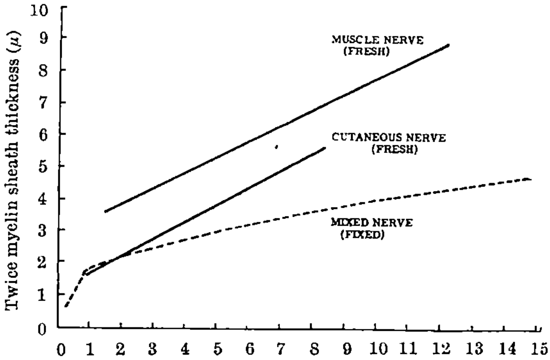

Fig. 1. Composite graph of twice myelin sheath thickness against axon diameter for a muscle nerve and a cutaneous nerve of the rabbit. A line derived from Sanders (ref. 4) for fixed and stained fibres of the mixed peroneal nerve of the rabbit is included for comparison

The lines representing fresh muscle and cutaneous nerves (Fig. 1) are calculated regression lines which have been tested for goodness of fit. The standard error of estimate of sheath thickness from axon diameter is 0·49μ and 0·57μ for the gastrocnemius muscle nerve and the sural nerve respectively. Full results, scatter diagrams and a statistical analysis will be published elsewhere.

It can be concluded that within the range of fibres studied: (1) in both muscle and cutaneous nerves a linear relationship exists between myelin sheath thickness and axon diameter; (2) the ratio of axon diameter to sheath thickness differs in cutaneous and muscle nerves; (3) the similarity in slope demonstrates that a unit increase in axon diameter is accompanied by an increment of sheath thickness which is similar for muscle and cutaneous nerves; (4) differences in slope and position of the line derived from Sanders[4] may be interpreted as resulting from admixture of muscle and cutaneous fibres in the peroneal nerve and the differential shrinkage inherent in processing.

The observed differences between muscle and cutaneous nerves make it desirable to investigate the effects of processing on each type of nerve separately. Such experiments are in progress.

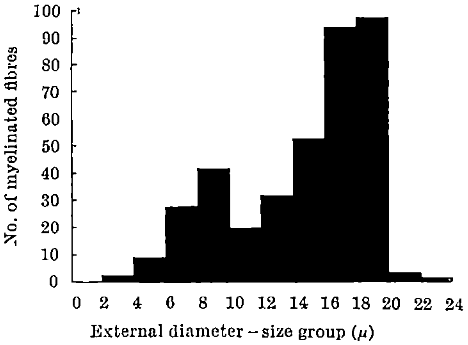

Fig. 2. External diameter-size frequency distribution of nervus gastrocnemius medialis of rabbit, exhibiting bimodality

A histogram (Fig. 2) illustrating the external diameter – size frequency distribution of the nervus gastrocnemius medialis of the rabbit prepared from a 5μ, fresh, transverse section, exhibits the typical bimodal form which has been demonstrated for fixed and stained preparations[5]. If, however, a histogram illustrating the internal diameter – size frequency distribution is constructed in a similar manner a unimodal form results (Fig. 3).

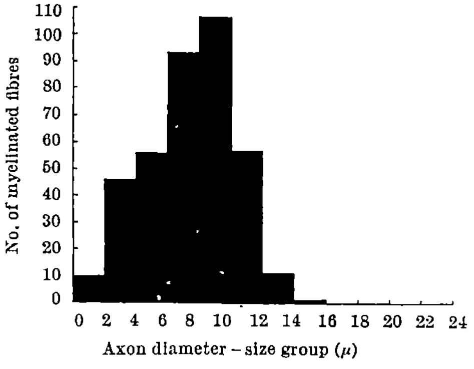

Fig. 3. Internal diameter – size frequency distribution of nervus gastrocnemius medialis of rabbit, exhibiting unimodality

In conclusion we wish to stress the following points: (1) histological techniques in current use should be subject to more critical evaluation; (2) our present results should be considered in investigations into impulse conduction, and the processes of growth and regeneration; (3) for many purposes simple external diameter measurements are inadequate; (4) for a more comprehensive study one should consider the interrelation between external diameter, internal diameter, internodal distance, and features of the nodal apparatus for a specific fibre population.

Giant Nerve Cells and Fibres in *Arenicola claparedii* (Polychæta)

OUR knowledge of the giant nerve cells and fibres of the Arenicolidae still rests on the pioneer work of Gamble and Ashworth[1]. These authorities described the structure and arrangement of the giant cell system in considerable detail and stated that they found it in all the species with one exception: "In *A. claparedii* there is, curiously enough, no trace either of giant cells or of giant fibres". They gave no details of the observations on which the statement just quoted was based, and no figures of the minute anatomy of the nerve cord in *A. claparedii*.

The conclusions of Gamble and Ashworth were accepted by later writers[2]. However, I recently decided to check the absence of giant nerve cells and fibres in *A. claparedii* because of the lack of detail on this point in their publication. It is, of course, well known that giant nerve cells and fibres are structures of great functional importance, and as all the tailed lugworms appear to live in much the same way, their absence in one only of the species would indeed be remarkable if it were true.

My observations were made on Neapolitan material. Transverse and sagittal serial sections were cut. They show giant fibres and giant cells arranged in the manner usual in the Arenicolidae, except only in one respect mentioned below. The structures approach those of other species in size. The cell in the accompanying photograph of a sagittal section has a cell body measuring 0·038 mm. by 0·029 mm. and a nucleus 0·013 mm. in diameter. In *Arenicola marina*, according to Gamble and Ashworth[1], "The cells measured 0·04 mm. in length and about 0·02 mm. in breadth".

The peculiarity of *A. claparedii* is that its giant cells lie in an unusually lateral position, as shown in the transverse section shown in Fig. 1. In other species, they occupy a nearly mid-ventral position within the cord. This may be correlated with a difference in the position of the cord as a whole, which lies deep to the circular muscle layer in most species, but outside that layer and in close contact with the epidermis in *A. claparedii*. If it may be sup-

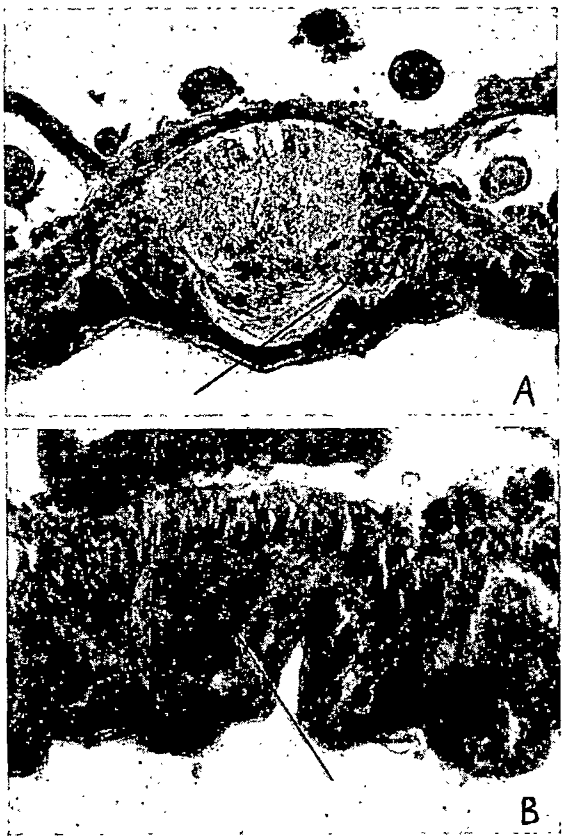

Fig. 1. *A*, transverse section through the nerve cord and surrounding tissues of *Arenicola claparedii*, showing two giant fibres (median, at the upper surface of the cord) and a giant cell (indicator line). *B*, sagittal section to show a giant cell. In each picture the length of the indicator line corresponds to 0·1 mm.

posed that Gamble and Ashworth sought the giant cells in sagittal sections cut through the main, fibrous part of the cord—a method that succeeds with any other species—their failure to detect the cells in *A. claparedii* can be explained; for sagittal sections must be cut to one side of the main mass of the cord if they are to pass through the giant cells in that species.

Anti-brucella Phage

ANTI-BRUCELLA phage was discovered by the Russian workers Drozewkina[1] and Viershilova (private communication; 1956) who isolated it from manure and old cultures of *Brucella*. They demonstrated an influence of the phage on the dissociation of *Brucella* and suggested that mutation in *Brucella* was due to the action of the phage.

We have isolated fourteen brucella phages from our own collection of 200 strains of *Brucella* and compared them with the Russian phage with regard to (*a*) morphology, (*b*) influence on dissociation of *Brucella* and (*c*) their effect upon different types of *Brucella*.

Anti-brucella phage was searched for in old cultures of *Brucella brucei* in the following way. Small pieces of agar with the old brucella culture were added to new 6-hr. cultures of *Brucella brucei* *S*19 on Huddleson's liver medium. After 48 hr. in a thermostat and 24 hr. in a refrigerator, we removed a few drops of material and added them to new 6-hr. cultures of *Brucella brucei* *S*19.

This procedure was repeated ten times. Next, this material was filtered and treated with chloroform. It was then tested for phage on the standard strains of *Brucella* (*bovis*, *melitensis* and *suis*) on Braun's medium. In this way, we obtained phages, which were examined in the usual way for lytic titre.

Preparations for electron microscopy were obtained by centrifuging the cultures for 1 hr. at 18,000 r.p.m. They were shadowed with chromium.

Using the electron microscope (giving a magnification of 16,000) the phage appeared as a round elementary body, 60–80 mμ in diameter but with no tail. *Brucella* cells showed characteristic features of phage lysis (Fig. 1).

When phage begins to act on *S Brucella* colonies, a picture is obtained giving evidence of a process of dissociation into *R* and *I* forms. Using Braun's method[2], the radiating layers of *R* phase on the base of *S* colonies may be observed. This known type of colony described by Huddleson[3] appears, therefore, to arise from phage modification.

Using Henry's technique[4], we have also observed flat colonies with frayed margins around which numerous micro-colonies appeared, an observation also made by the Russian workers (ref. 1 and Viershilova, private communication; 1956). Another type of colony observed was the flat granular type.

The Russian phage did not lyse *Brucella melitensis* or *Br. suis* from our collection, neither did it have any effect on the *suis*-type strains received from Denmark, Czechoslovakia, America or the standard F.A.O. W.H.O. *suis* No. 1330. The Russian phage lysed typical *Br. abortus* strains (Fig. 2), but no lysis

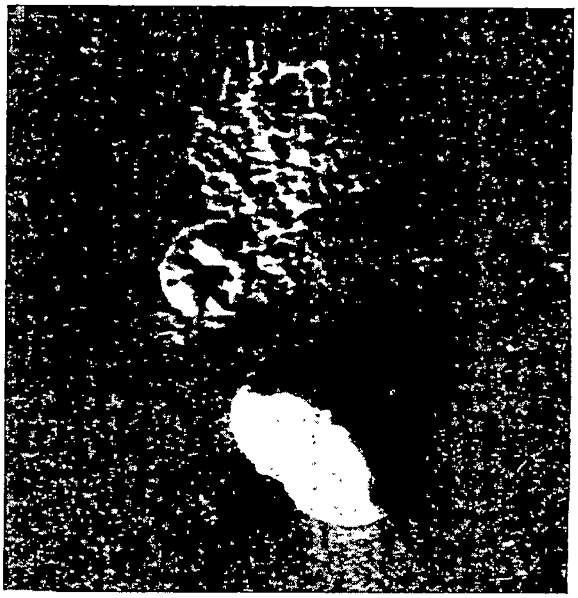

Fig. 1. *Brucella brucei* and phage. (× 16,000)

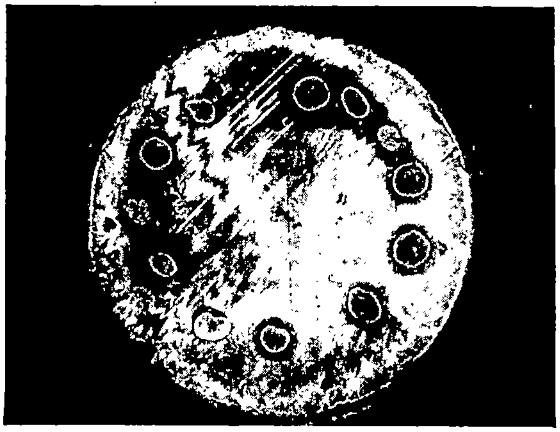

Fig. 2. *Brucella brucei* (*bovis* 544) and fourteen races of phage (−) → (+++)

occurred when atypical strains (for example, strains differing from the standard F.A.O. W.H.O. strain 544) were exposed to the action of the same phage. However, it was observed that the specific action of the phage on *Br. abortus* changed; this involved both the phages and the *Brucella* strains. The fourteen phages isolated by us did not lyse either *melitensis* or *suis* strains. Further investigations are in progress.

Work is proceeding on the phage typing of *Brucella* strains comparable to the phage typing of the salmonellas, shigellas and staphylococci.

An Electron-Microscopic Study of the Ciliature of the Trochophore Larva

THE trochophore larvæ of marine polychæte worms present several ciliary structures convenient for comparative study.

From an electron microscopic study of the equatorial band (prototroch), which has a motor function, the following conclusions were drawn (figures in parenthesis refer to Figs. 1 and 2).

The structure of the external stem of the cilium as a ring of nine peripheral fibrils around a central fibril was confirmed (1).

At certain places the ciliary membrane, less dense and much thinner than the fibrils, encloses intraciliar swellings (2), apparently of ordinary cytoplasm. This ciliary membrane is continuous with the cellular one (3).

Before penetrating the cell, the cilia pass through pores in the cuticle, which consists of two layers (5 and 7) connected at several places (6). Between the cuticle and the outer cell membrane there is a large extracellular space (4) in which the cilia are connected with the segments arising from the basal bodies (8).

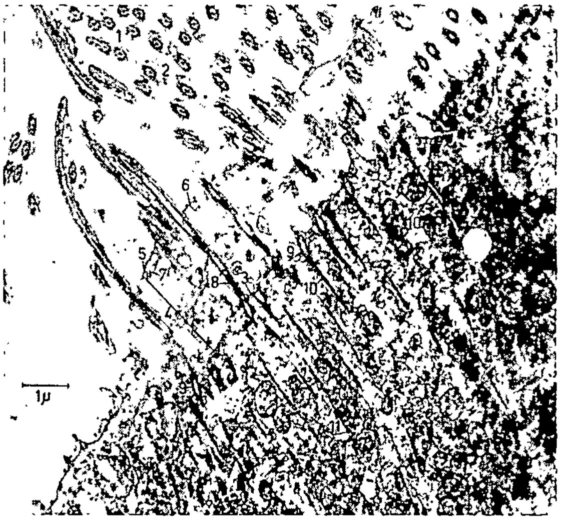

Fig. 1. Equatorial band of Trochophora (× 7,500). (1) Kinocilium, transverse section; (2) intracillar swelling; (3) cellular membrane; (4) extra-cellular space; (5) external layer of the exoplate; (6) connexion; (7) internal layer; (8) basal body; (9) basal body; (10) rootlet; (11) mitochondria

The basal bodies (9) are nearly symmetrical, hollow and somewhat swollen in the centre. The rootlet (10) seems to sprout from the basal bodies and has a periodic structure, with an interval of about 600 A. Numerous mitochondria (11) are found close to the rootlets, which become narrower toward the end.

A narrow slit occurs between the top of the basal body and the ring (above 8) in which the nine fibrils of the stem end. The central fibril stops above this ring. Another ring, with nine external bristles, looking like a cog-wheel, is formed by the nine fibrils while crossing the external structure described above. The name 'exoplate' is suggested for this external formation, which envelops the whole trochophore like a bag, stretched around the cilia, folded elsewhere. This bag finishes in the stomodæum, where it is replaced by microvilli, standing like a palisade between the bases of the endodermic cilia.

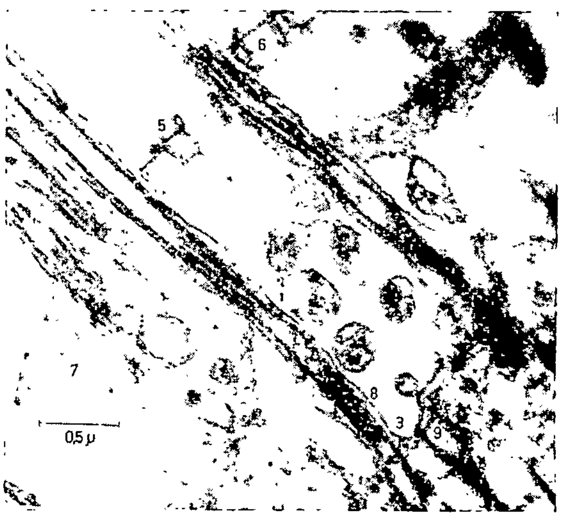

Fig. 2. Kino-cilia (part of Fig. 1) (× 30,000)

The trochophore larva shows a non-stop whirling motion in a spiral path through the fluid. The basal bodies, closely packed in the mid-line of the prototroch, form a semi-rigid structure, on which the cilia beat rhythmically. The beats result from contractions of the rootlets; during these contractions the outer part of the cell, under the ring of the basal bodies, is shortened. This compression acts on the hollow tube of the basal body, unfolding it and drawing the stem into a pendular motion.

The nine columns give rigidity to the stem, which can attain a length of 100μ for a diameter of 0·3μ. The exoplate ensures regularity in the spacings of the stems; its elasticity ensures the return of the cilia after movement. Hydrodynamic adjustment is made by continuous variation of the body's form: the looseness of the exoplate permits this under the control of the ciliary bands.

In slowing down, the whirling motion is neutralized by lateral bands of cilia, near the main moving band: in each cell the rootlets point in the same direction. Knowing how the equatorial band moves, we can deduce its function through the position of the cilia on the electron-micrographs, each cell being a functional unit.

A sagittal section of the main equatorial band (prototroch) reveals five different parts: the first and second decide the form of the animal; the third and fifth can, by fanning out, open and shut off the operating space of the fourth band, which forms the main motive organ.

A similar arrangement appears in the perianal band (telotroch), with a pars motoria working as a screw, and a pars plastica, over less compact cytoplasm, changing the form of the animal.

If we consider that the larva has to maintain a constant rhythm, each cell being sensitive to this pattern, the structures studied above explain how it is regulated. The role of the nerve is to give the tempo by a continuous wave of activation.

Gibberellic Acid and Vernalization

Several workers[1,2] have reported that treatment with gibberellic acid induces early flowering in certain biennial plants in the same season and thus replaces their normal low-temperature requirement. In these biennial plants, extension growth and flowering go hand in hand, and it is quite likely that gibberellic acid replaces vernalization treatment incidentally, by bringing about the former, which is an almost universal action of the chemical. In the present investigation this suggestion has been tested by determining the effect of gibberellic acid on the flowering of both vernalized and normal plants of *Brassica campestris* L., *Cicer arietinum* L., *Linum usitatissimum* L. and *Lens esculanta* Moench, none of which has any obligatory low-temperature need for flowering. In *Brassica*, the reproductive process is associated with a change in the growth habit of the plant from that of rosette formation to stem elongation, while in the rest it is not so.

Treatments consisted of: (1) post- and pre-vernalization soaking and soaking of normal seeds for 8 hr. at the room temperature and (2) one or several sprayings to run-off, and dropping on the youngest leaf at the apex, at different stages of growth, of both vernalized and normal plants, 100, 25 and 1 p.p.m. aqueous solutions of gibberellic acid. Records of the average time taken from sowing to anthesis and of the number of leaves developed on the main axis before the appearance of the first flower bud were kept.

Leaves on the treated plants of *Cicer* and *Linum* developed slight chlorosis and on the former there was overcrowding in the apical region at an advanced age.

Spraying and dropping treatments with 100 and 25 p.p.m. of gibberellic acid brought about an extra growth in length in both vernalized and normal plants of *Cicer* and *Lens*, but there was scarcely any effect on *Linum*. In *Brassica*, an early elongation of the shoot was recorded only in the unvernalized plants, but there was barely any difference in the final height of the treated and untreated ones. Rudimentary flower buds could be detected in both normal and vernalized plants of *Brassica* as soon as the shoot started to elongate, but in the plants treated with gibberellic acid this is possible only when they attain a certain height. This confirms the findings of several workers[1–3]. Statistically significant earliness in flowering was obtained only in unvernalized plants of *Brassica* subjected to repeated applications of 100 p.p.m. of gibberellic acid (Table 1).

In the present investigation, seed treatments of all the four plants with gibberellic acid failed to produce any earliness in flowering; hence it may be concluded that this chemical does not replace 'vernalin'. Application of gibberellic acid to growing plants, too, is effective only in *Brassica*, but the degree of earliness induced is rather poor when compared with that resulting from chilling. Thus, for example, in the sowing of October 4, 1957, gibberellic acid treatment brings about an earliness in flowering of 8·0 days, and a reduction of 1·2 in the number of leaves; for plants raised from maximally vernalized seeds the corresponding figures were 23·1 days and 7·3.

Induction of early flowering is one of the many effects of vernalization. Among others, mention may be made of stem elongation in certain rosette-forming plants and several morphological changes, such as the shortening of the first leaf in winter wheat and rye, change in the shape and margin of the leaves in *Cichorium intybus* and a diminution in the length of the hypocotyl and area of the cotyledonary leaves

Table 1. Effect of a 100-p.p.m. Aqueous Solution of Gibberellic Acid on the Flowering of *Brassica campestris* L. Number of Plants are given in Brackets

Date of sowing	Mode of application	Time taken for anthesis in days		Leaf number	
		Gibberellic acid	Control	Gibberellic acid	Control
Aug. 24, 1957	5 sprays, one every 3 days, starting at an age of 5 days	52·5 (13)	60·8 (16)	16·1 (13)	18·1 (16)
Oct. 4, 1957	7 drops, one every 3 days, starting at an age of 7 days	50·8 (21)	58·8 (20)	16·0 (15)	17·2 (12)
Nov. 5, 1957	3 sprays, one a week, starting at an age of 7 days	65·1 (20)	71·5 (12)	14·9 (20)	16·9 (12)

in *Phaseolus radiatus*. In annual plants like *Cicer*, *Linum* and *Lens*, the early floral initiation is scarcely associated with an extra elongation of the stem of the type met with in the biennial plants. In the rosette-forming brussels sprouts, Verkerk[4] has demonstrated that stem elongation and flower initiation are two separate actions of the vernalization treatment. In gibberellic acid treatment also these two actions are separate, but a fundamental difference exists between the vernalization and gibberellic acid effects, as in the former, the flower buds become visible almost simultaneously with that of extension growth, while in the latter it is not so[2,3,5].

This investigation is further support[6] for Lang's suggestion that the primary effect of gibberellic acid is on stem growth, flower formation being brought about indirectly.

I am greatly indebted to Eli Lilly and Co. for the supply of gibberellic acid used in these experiments.

Response of Cacao to Fertilizers

Cunningham and Lamb[1] have recently described an experiment in Ghana which demonstrated the response of cacao to fertilizers both with and without shade. These results serve to confirm more intensive studies, made at the Imperial College of Tropical Agriculture in recent years, which have resulted in the development of a general theory of the interaction of shade and nutrition in the growth and cropping of young cacao.

A statistically designed field experiment was planted using an artificial shade of slats to let through different percentages of full sunlight. Each shade treatment carried a 2 × 2 × 2 factorial nitrogen–phosphorus–potassium layout with the fertilizers present or absent. Clonal cuttings were used as planting material.

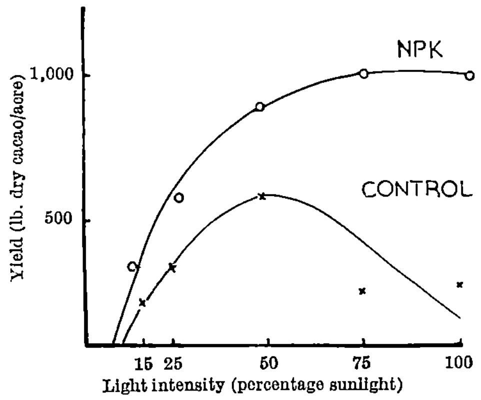

Fig. 1. Relation of yield (lb. dry cacao/acre) to light intensity for control and fertilizer plots

The yields at three years of age for the control and fertilizer plots are shown in Fig. 1. From this it is clear that with light intensities less than some 50 per cent of full light, light is limiting to yield. At more than 50 per cent light, however, the drop in yield of the control plots as compared with the increasing yield of the fertilizer plots indicates that nutrition is now limiting to yield. The results have been described in detail by Evans and Murray[2] and by Murray[3], together with the effects of shade removal and such changes in leaf analysis as occur under different shade conditions.

It is obviously impossible to consider either the shade or the nutritional requirements of cacao independently. In addition, the relationship is dynamic, varying with increasing size of tree and consequent self-shading. This interaction of light intensity with the nutritional status of the tree is of great importance in the agronomy of the crop.

Yield Variations in Tree Crop Experiments with Specific Reference to Cacao

In the past, large yield fluctuations within treatments in cacao fertilizer experiments have proved difficult to understand. These fluctuations, frequently occurring between adjacent trees, necessitate an unwieldy degree of replication before a sensible level of error variance is obtained within the experimental area. It is important to know the cause of these fluctuations, not only to reduce to a minimum the acreage required for field-experimentation with cacao but also to help in understanding the behaviour of tree crops and of cacao in particular.

Results from the long-term fertilizer trials on cacao conducted by this Department[1] have now shed some light on this problem. Thus in Fig. 1 mean cacao yields of *ICS* 1 clones obtained during the sixth, seventh and eighth years since these trials were planted, have been plotted against tree girths at 3½ years of age. The degree of correlation between these two factors was highly significant (at $P = 0{\cdot}001$ level).

It is clear from this relationship that, so far, the yielding capacity of the trees and the variation in yield have been largely determined by uncontrolled variables operative during the first few years following the establishment of the experiment. The effect of these variables was reflected in the varying measurements of girth at 3½ years of age. It is suggested that these variables are associated with traditional methods of cacao establishment.

Traditionally, young cacao is permitted a heavy degree of ground shade while its root system is attaining vigour. This is sensible, except that in practice these conditions deteriorate into heavy bush encroachment. In cacao-growing areas where there is a marked dry season—as in Trinidad—this inevitably means intense competition for soil moisture as well as nutrients. If weed competition and soil

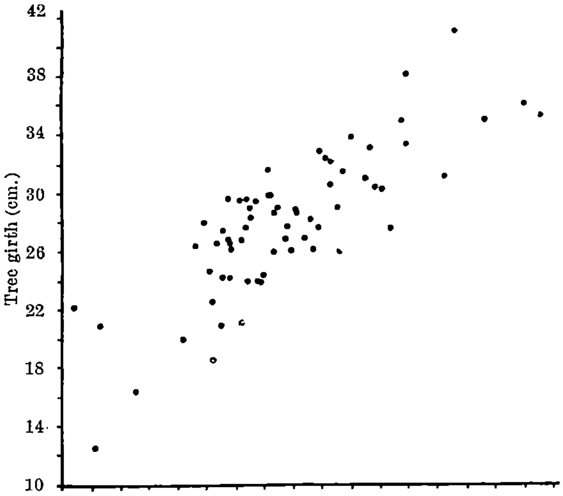

Fig. 1. Cacao tree size/yield correlation ($r = 0{\cdot}810$: for $P = 0{\cdot}001$ $r = 0{\cdot}380$)

moisture deficits are not controlled during the early stages of establishment—and Fig. 1 suggests that young cacao is particularly sensitive to adverse factors in its environment—then extreme variability in yield can be expected later.

Fig. 1 implies that traditional procedure is infringing a fundamental principle of plant science. This principle simply contends that a check to development in plants is permanent and cannot be rectified by later attempts at amelioration. The same principle has also been recognized to a restricted extent in animal studies[2], and its general acceptance lays emphasis on good management for precise control of field experiments. It has, too, equally relevant practical importance in good farming and successful agriculture.

From the point of view of plant science, it raises a critical issue in the measurement of fertilizer response. If the evaluation of fertilizer response at a given site is to be scientifically unimpeachable, then environmental effects—and the word environment is used in its fullest implication—must all operate in the direction of improved plant-growth. The net effect on plant-growth of all individual environmental effects is the algebraic sum of those effects. If any single effect is unintentionally given a negative sign, limitations to growth will be other than those intentionally imposed within the limits of the statistical layout used. The arithmetical order of an environmental factor with a negative sign may completely swamp response to a fertilizer. This has certainly been the case in many fertilizer experiments on cacao in the past.

A full account of this work will be reported elsewhere.

The Macronucleus of *Spirostomum*

The purpose of this communication is to describ an interesting property of the macronucleus of species of *Spirostomum*, a large freshwater ciliate The nuclear apparatus of this animal consists of long cylindrical macronucleus and a number of smal micronuclei. The cytology of this species has bee described by Seshachar and Padmavathi[1]. Feulge preparations show a number of granules of varyin sizes in the macronucleus embedded in a more homogeneous matrix.

During certain regeneration experiments in thi laboratory, it was noticed that the macronucleus i highly extensile and could be stretched to a grea length. An easy and simple method was to hold on end of the animal down on a slide and pull the othe end with a needle. The body ruptures, but th macronucleus can be pulled out until a long, thi strand results. A number of such attempts wer made and were almost always successful, and severa macronuclei pulled to varying lengths were obtained They were then fixed and stained with Feulgen Fig. 1 shows: (*a*) the normal macronuclei of th vegetative animal, and (*b*) a nucleus partiall stretched. One macronucleus was pulled to such length that five separate photographs had to b taken to include the whole. [This photograph wa too long for reproduction on the same scale as th others.—Editors.] The maximum length to whic a 0·18-mm. macronucleus could be pulled out wa nearly 2·72 mm., which is more than fifteen time the original. Further stretching almost alway resulted in its snapping.

Similar observations were made on another species, *S. ambiguum*. In this species, the macronucleus i moniliform, with clear swellings and slender connexions between them. When stretched, the lengthening occurs at the expense of the swellings an the resulting body is a greatly elongated unifor strand.

This is probably the first record of the nucleus o any animal cell displaying such remarkable extensil properties. Recent examination with the electro

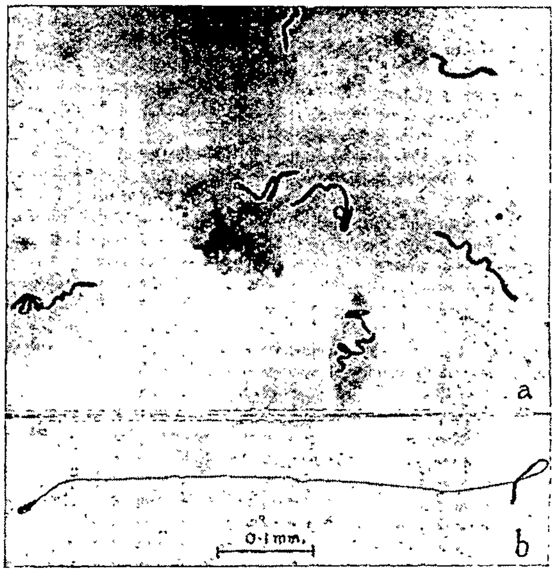

Fig. 1. Photographs of Feulgen preparations of the macronucleus of *Spirostomum* sp. (*a*) Nucleus of normal vegetative animal; (*b*) nucleus partially stretched

microscope has shown that the ciliate macronucleus, like the nucleus of other more typical cells, possesses a double membrane with perforations[2]. The amphibian oocyte nucleus, which was among the first to be examined with the electron microscope[3], has a membrane which readily ruptures under the slightest pressure and is presumably different from that of the macronucleus, which must have remarkable powers of resistance to mechanical manipulation and great extensile properties. It would be interesting to see how the nuclear membrane is accommodated to the stretching possible in *Spirostomum*. That a bounding membrane exists, even in this maximum stretched state, seems beyond doubt.

Embryology of *Atkinsonia ligustrina* (A. Cunn. ex F. Muell.) F. Muell.

The embryology of *Atkinsonia ligustrina*, a root parasite of the Loranthaceae[1] endemic to Australia, has so far remained uninvestigated. The present account is based on a study of some specimens of this plant kindly sent by Prof. H. S. Mckee of the University of Sydney.

The first important point arising from this work concerns the nature of the calyculus. In the Loranthaceae this is generally devoid of a vascular supply, and its morphological nature has consequently been much debated. Roxburgh[2] and Bentham and Hooker[3] considered it to be a true calyx and Danser[4] conceded the same "on practical grounds". On the other hand, Eichler[5] considered it to be an axial structure, and this view was supported by Engler and Prantl[6] and by Schaeppi and Steindl[7]. Narayana's[8] report concerning the presence of vascular bundles in the seven-toothed calyculus of *Nuytsia floribunda* supports Bentham and Hooker's view of the sepaline nature of the calyculus. The feeble vasculature in the calyculus of *Atkinsonia* (Figs. 1 and 2) appears to be a connecting link between *Nuytsia* and the other Loranthaceae in which the calyculus is devoid of a vascular tissue.

Atkinsonia also differs from most other Loranthaceae in having spherical pollen grains (Fig. 3). The only other plant of the family which shows a similar condition is *Tupeia antarctica*[9,10].

In the development of the embryo sac a six-nucleate stage (two nuclei in the upper end of the gametophyte and four in the lower) precedes the usual eight-nucleate condition. The four nuclei at the upper end give rise to the egg apparatus and the upper polar nucleus. Three out of four nuclei at the lower end organize themselves quite early into the antipodal cells, whereas the fourth functions as the lower polar nucleus. As in *Macrosolen*[11], the lower end extends downward leaving behind the antipodals *in situ*. The upper ends of the embryo sacs extend to the base of the style and often show one or two small apical extensions, which probably have a haustorial function.

The fusion of the polar nuclei always takes place below the egg. The first division of the zygote is vertical and subsequent divisions are transverse, resulting in a biseriate pro-embryo. Due to the elongation of the suspensor, the embryo is pushed downward into the collenchymatous tube (Fig. 4). The endosperm is cellular and, as in other Loranthaceae, the endosperms of all the embryo sacs unite to form a composite structure with eight deep lobes in the mature fruit.

The pericarp comprises the outer leathery coat followed by the viscid layer, a zone of several layers of sclerotic cells, and the crushed vascular tissue (Fig. 5). The sclerotic zone, which is responsible for the drupaceous nature of the fruit, is uncommon in the Loranthaceae.

Our knowledge of the subtribe Gaiadendrinae, which includes only two genera—*Atkinsonia* and

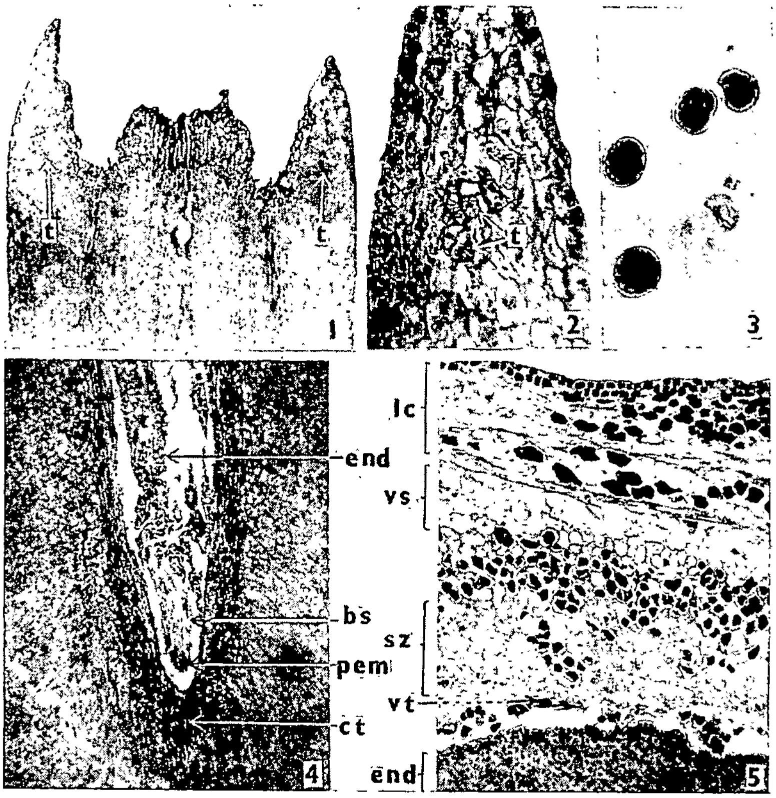

Fig. 1. Long. section of the upper part of ovary showing tracheids in the calyculus (× 33). Fig. 2. Magnified view of tracheids (× 8). Fig. 3. Pollen grains (× 126). Fig. 4. Part of ovary showing the pro-embryo with a broad suspensor (× 37). Fig. 5. Portion of pericarp (× 30). (Key: *bs*, broad suspensor; *ct*, collenchymatous tube; *end*, endosperm; *lc*, leathery coat; *sz*, sclerotic zone; *t*, tracheids; *vs*, viscid layer; *vt*, vascular tissue)

Gaiadendron—is very meagre, and it is likely that *Gaiadendron* may also show some interesting points.

The spherical shape of the pollen grains and drupaceous nature of the fruit suggest a close relationship between the Loranthaceae and the Santalaceae.

In recent years the embryology of many members of the Santalaceae (*Comandra, Exocarpus, Leptomeria, Mida. Osyris, Santalum* and *Thesium*) and Loranthaceae (*Amyema, Barathranthus, Helicanthes, Lepeostegeres, Lysiana, Macrosolen, Nuytsia, Peraxilla, Tapinanthus, Tapinostemma, Taxillus* and *Tolypanthus*) has been studied in this Department. It would be greatly appreciated if fellow botanists will help in procuring specimens of *Buckleya, Choretrum, Fusanus, Myoschilos, Nestronia, Omphacomeria* and *Pyrularia* of the Santalaceae, and *Aëtanthus, Diplatia, Gaiadendron, Hyphear, Psittacanthus* and *Tupeia* of the Loranthaceae.

I wish to thank Dr. B. M. Johri and Prof. P. Maheshwari for valuable suggestions and comments.

Purification and Serology of Cucumber Mosaic Virus

CUCUMBER mosaic virus causes many important plant diseases and occurs as a group of strains differing in their host-range, symptoms produced, transmissibility and other properties. Few studies have been reported on the serological relationships among these strains, possibly because of their labile nature *in vitro* and their low concentration in the host plant. In crude host extracts the virus becomes non-infectious when stored for a few days or when diluted to approximately 10^{-3}. The strain relationships have been studied previously by cross-protection tests. Although antisera to cucumber mosaic virus[1,2] have been claimed, later attempts[3] were unsuccessful. Antisera of low titre have been obtained to tomato aspermy[4,5], a virus related to cucumber mosaic virus.

A strain of cucumber mosaic virus previously described[6] has now been partially purified and used to produce an antiserum. The purification procedure was as follows. The virus was cultured in leaves of tobacco plants (*Nicotiana tabacum* L. var. Havana 425) mechanically inoculated with sap of corollas from infected cucumber plants. Inoculated plants were grown at 24–30° C. in a glasshouse from May until October. The inoculated leaves were harvested, the mid-veins removed and the tissue homogenized at 3° C. in 0·5 *M* potassium phosphate buffer (*p*H 7·5) containing 0·1 per cent thioglycollic acid (1·25 ml. of buffer for each 1·0 gm. of leaf tissue). The homogenate was squeezed through a glass-wool pad and *n*-butanol was added dropwise to the constantly stirred filtrate to give a concentration of 8·5 per cent. The mixture was stirred for a further 30 min. during which time the chloroplastic material was precipitated. The precipitate was separated by centrifuging at 5,000 r.p.m. for 10 min. and the clear, amber-coloured supernatant was filtered through glass-wool. The virus was sedimented by centrifuging the filtrate at 30,000 r.p.m. for 2 hr. in a No. 30 rotor of a 'Spinco' model *L* ultracentrifuge. After ultracentrifugation the supernatant was discarded, the centrifuge tubes drained and the pellet in each tube dispersed in 0·5 ml. of 0·05 *M* potassium phosphate buffer at *p*H 7·5. Resuspension of the virus was continued by mechanical shaking for 2 hr., after which the suspension was clarified by centrifugation at 5,000 r.p.m. for 10 min. The faintly opalescent supernatant containing the virus was carefully withdrawn.

The virus preparations were assayed for infectivity by inoculating the young, expanding primary leaves of cowpea (*Vigna sinensis* Endl. var. Black) on which necrotic local lesions developed, usually within 24 hr. The dilution end-point of the virus in these preparations varied from 10^{-3} to 10^{-6} when diluted in 0·05 *M* buffer. The longevity of the virus in these preparations was greater than that generally reported[7]; one preparation was infectious after 45 days when stored at 3° C. The infectivity in this case, however, was about one-half of that of the freshly purified virus.

Rabbits were injected intravenously at four to five day intervals with 4 ml. of virus prepared as described. Injections were repeated six times and the rabbits were bled six days after the last injection. When the rabbit serum was used for precipitin tests with the virus, a positive reaction was obtained at serum dilutions up to 1/1024.

Cucumber mosaic virus, purified as described, was prepared in various ways for electron microscopy and compared with similarly treated control preparations from healthy tobacco leaves. Samples were sprayed on to collodion-coated electron microscope grids and allowed to air dry. The specimens were shadowed with uranium. When examined with an *RCA* type electron microscope, the grids sprayed with the virus preparations showed numerous, uniform spheres with a mean diameter of 40 mμ. These spheres were not found on grids sprayed with the control preparations. These observations are in agreement with previous work[6] on the shape of cucumber mosaic virus.

Full details of this work will be published later. We wish to express our thanks to Dr. P. Kaesberg, Mr. Bockstahler and Mrs. Sachs of the Department of Biochemistry, University of Wisconsin, for the assistance given with the electron microscope studies.

Observations on the Spread of Mouse Polyoma Virus Infection

The tissue culture growth of the mouse parotid tumour virus, referred to by Stewart *et al.*[1] as "SE polyoma virus", has led to the development of rapid methods for its demonstration and determination, and to practical and specific serological techniques for antibody determinations as well[1-5]. We have made preliminary observations on the distribution of antibodies in various mouse colonies and on the excretion of virus.

Uninoculated mice of six breeder colonies were bled individually, and the sera tested for complement fixing and hæmagglutination inhibiting antibodies, the latter test using 16 hæmagglutinating units. Close correlation was found between the two tests[6]. Hæmagglutination inhibitory antibody at 1 : 200 or greater, or at 1 : 100 in serum treated with receptor-destroying enzyme of *V. cholera*, was considered positive. Table 1 summarizes the frequency with which antibody was detected in mice of the various colonies. Three colonies appeared completely free of infection, while the others had infection in almost all strains tested. Antibody was found predominantly in mice more than three months of age. No evidence of strain specificity of infection was observed; for example, adult *AKR* mice had infection-rates ranging from 5 to 100 per cent in the three infected colonies, while none of 84 adult *AKR* mice in the Jay–Poiley colony was positive.

Table 1. INCIDENCE OF ANTIBODY TO POLYOMA VIRUS IN SIX MOUSE COLONIES

Colony	No. of of mice positive/No. tested		No. of strains or sublines positive/No. tested
	1–3 months old	>3 months old	
Andervont (N.I.H.)		0/95	0/4
Gross (New York)	1/61 (2 per cent)	49/58 (84 per cent)	4/5
Jackson Memorial Laboratory (Bar Harbor)	1/53 (2 per cent)	5/85 (6 per cent)	3/4
Jay–Poiley (N.I.H.)	0/539	0/536	0/19
Law (N.I.H.)	5/120 (4 per cent)	149/406 (37 per cent)	15/16
Microbiological Associates (Bethesda)		0/62	0/3

It is probably significant that two of the three ıegative colonies are maintained in separate quarters ınd by personnel who do not handle experimental nice, while the three infected colonies are located)hysically in proximity to experimental colonies and vork with polyoma virus and mouse leukæmias, and ıre cared for by the same personnel. In the Law :olony, antibody-rates in uninoculated mice 6–11 nonths old were 59 per cent (36/61) in mice in the 'oom with new-born mice inoculated with polyoma 'irus, 39 per cent (36/92) in the room with adults vhich received the virus as new-borns, and 13 per cent 13/101) in a room which does not house animals noculated with virus. Also, mice brought into our aboratory from the Jay–Poiley colony as new-borns nd inoculated with uninfected control tissue culture luids have become antibody positive after 4–6 months n about 30 per cent of individuals tested.

In the Law colony, serological conversions in mice e-bled after 2–4 months were somewhat more requent in mice one to five months of age when bled iitially (19 of 48 converted) than in mice more than x months old (12 of 47 converted).

To determine the source of the apparent environmental contamination, the following tests for virus were made. Urine and mouth swabs were taken from 8 mice which had been inoculated with virus as new-borns five to ten weeks previously; these mice were in five different cages, and the bedding and drinking water of each cage were also sampled. The virus detection procedure employed was based on the production of antibody in adult mice inoculated intraperitoneally (mouse antibody production test): this procedure has been found to be highly sensitive for detection of virus[6]. A suspension of the material tested was inoculated intraperitoneally into three weanling mice from the Jay-Poiley colony, and three weeks later their sera were tested for hæmagglutination-inhibiting antibody. 84 control mice inoculated with saline were distributed in the jars with the test mice, and none developed antibody. Seven of the eight urine specimens were positive for virus, as were all eight mouth swabs, all five bedding samples, and four of the five drinking bottles.

Inhalation may be the means of entry, since we have found that mice can be infected as new-borns or adults by intranasal instillation of 10^2 to 10^3 intraperitoneal immunizing doses, but as yet we have not been able to infect by feeding.

These results suggest that environmental contamination is important in the spread of polyoma virus, and that cross-infection is to be expected in laboratories working with the agent. The implication that infection is generally acquired at several months of age would explain the rarity of spontaneous occurrence of the characteristic parotid tumours, even in infected colonies[7,8], since, experimentally, tumours can be produced only by inoculation of suckling mice. The great variation in polyoma infection-rates in various *AKR* stocks indicates that polyoma virus bears no etiological relation to spontaneous *AKR* leukæmia, despite their repeated association[8], since high leukæmia-rates are found in all *AKR* stocks.

Biochemical Changes in Virus-infected and Regenerating Mouse Liver

The biochemical changes accompanying the multiplication of an animal virus within its host cell are still largely unknown. Alterations in the levels of activity of a variety of enzymes in mouse brain infected with virus have been reported by Bauer[1].

Table 1

Enzyme	Activity ± standard error in livers			
	Normal	Infected 24 hr.	Regenerating 48 hr.	Infected 20 hr., regenerating 48 hr.
Succinic dehydrogenase	6·38 ± 0·28	8·52 ± 0·33	6·52 ± 0·44	6·34 ± 0·46
Xanthine dehydrogenase	1·39 ± 0·05	2·70 ± 0·11	2·33 ± 0·11	2·49 ± 0·28
Uricase	216 ± 16	283 ± 23	182 ± 30	185 ± 26
Acid phosphatase	69·9 ± 2·7	65·4 ± 6·6	80·4 ± 12·6	46·7 ± 2·38

In this system the number of infected cells is not known and the variety of cell types and possibility of compensatory changes in other neurones make interpretation difficult. Tissue cultures infected with poliovirus show marked changes in various enzyme activities[2], but here the considerable variation in physiological state of the culture produced by small experimental variations must be borne in mind when interpreting results. The effects of a virus on the cells of its natural mammalian host can be studied conveniently in the livers of mice infected with large (10^9–10^{10} *LD*50) intravenous inocula of ectromelia virus[3]. Simultaneous infection of almost all hepatic parenchymal cells takes place, there is no cellular infiltration, and up to 30 hr. after infection there is little or no necrosis. Mouse livers so infected show a progressive increase in size without cell division. The comparison between normal growth in regeneration and that induced by infection, of either normal or regenerating liver, is of some interest. In liver regenerating after partial hepatectomy increase in cell size is followed by cell division, but in regenerating liver infected with ectromelia mitosis is inhibited[4]. Other evidence for nuclear changes is decreased synthesis[5] of coenzyme I and decreased adenosine deaminase activity in both infected and regenerating livers.

There is, however, no evidence to date of synthesis of ectromelia virus by the nucleus. The effects of infection and regeneration on some cytoplasmic enzymes (succinic and xanthine dehydrogenases, uricase and acid phosphatase) have been measured. Activities (per gm. fat-free dry weight) are expressed as μmoles substrate destroyed per minute (dehydrogenases), μgm. uric acid destroyed per minute (uricase) or King Armstrong units (acid phosphatase) (Table 1).

The activity of the succinic dehydrogenase complex is an index of the mitochondrial content of a tissue. There is no change in succinic dehydrogenase activity in regenerating or infected regenerating livers. Since the fat-free dry weight of the regenerating liver fragment has increased by 40 per cent, this represents a synthesis of mitochrondria proportional to liver growth, even though in the latter case cell numbers are not restored. The increase in activity in infected intact livers, which also show cell growth, represents a more than proportional increase in the mitochondrial population of each cell.

Xanthine dehydrogenase activity, localized in the soluble fraction, is increased in both regenerating and infected livers. By its aldehyde oxidase activity[6] this enzyme may play a part in the metabolism of 2-carbon fragments. This would seem more likely than the alternative suggestion that purine catabolizing activity is causally related to increased nucleic acid synthesis.

Uricase activity is wholly, and acid phosphatase activity partly, associated with the lysosome fraction of the cytoplasm[7]. Changes in activity in regenerating livers are not significant. In infected livers uricase activity is increased while phosphatase is littl changed before 24 hr. In infected regenerating liver uricase activity does not differ from that of uninfected controls, while phosphatase activity fall markedly. These findings suggest a considerabl alteration in the composition of some subcellula fractions. Uricase/acid phosphatase ratios wer determined on three centrifugally separated fraction of the cytoplasm: heavy mitochondria, light mitochondria (including lysosomes) and a supernatan (including microsomes)[7]. The results (expressed i arbitrary units) are shown in Table 2. These finding may be due to either (*a*) changes in the enzymi composition of all members of a particle populatio which is otherwise little altered; or (*b*) selectiv damage to some members of a population in whic enzyme activity is unequally distributed.

Table 2

Cytoplasmic fraction	Uricase/acid phosphatase ratios in livers		
	Normal	Infected 24 hr.	Regenerating 48 hr.
Heavy mitochondria	7·9	5·9	8·1
Light mitochondria	9·0	10·0	8·8
Supernatant	3·4	1·5	2·8

Marked biochemical changes are induced in th cytoplasm by both infection and regeneration. Cel growth in regeneration may be considered to b normal and orderly, while that in infection is disorderly to the extent that it ultimately results in cel death. This disorder is reflected in difference between some of the changes in infected and regenerating livers. The mechanism of production of th changes in cells infected with virus is still obscure They may be a direct result of the presence of viru or virus components in the cell; or they may be secondary response to a change in emphasis of metabolic pathways, produced during the early stages o infection. Studies of the effect of shorter periods o infection may help solve this problem.

This work was supported by a grant from th National Health and Medical Research Council We wish to thank Mrs. I. M. Stephens for technica assistance.

Mutations in L-Forms

Conversion of bacteria into L-forms involves changes in physiology as well as morphology. Comparing sensitivity to drugs of L-forms and bacteria, we are struck by the much higher resistance of the former to penicillin. Strains of L-forms of *Proteus* used in our laboratory are able to grow in the presence of 60,000 units penicillin/ml. On the other hand, they are more sensitive to streptomycin, chlortetracycline and chloramphenicol than are the bacterial forms. Tulasne and Minck[1] found that stable L-forms of *P. morganii* were 8,000 times and unstable L-forms of *P. vulgaris* were 25,000 times more sensitive than the corresponding bacterial forms. Lederberg and St. Clair[2] showed a fifty-fold decrease in resistance to streptomycin after converting *Escherichia coli* to the L-form. The authors suggest that "this can be viewed as the negation of the S^R effect when the wall is stripped or a mutual reinforcement of penicillin and streptomycin in respect to another target". They were inclined to accept the former interpretation. Horoszewicz and Horoszewicz[3] noted the inhibitory action of streptomycin on the conversion of *P. mirabilis* to the L-form. In the presence of the antibiotic it was necessary to inoculate 1,800 times more bacteria to obtain the same number of L-colonies.

We have used a stable L-form of *Proteus mirabilis* subcultured more than 100 times on serum-agar and then adapted to charcoal-agar and lately to charcoal-broth[4]. Growth of L-forms in the charcoal media was much more luxuriant than in serum media. In charcoal-broth in 2–3 days, L-organisms formed a remarkable turbidity and some days later a thick, greyish pellicle which could be dispersed on shaking. Usually the number of L-colonies grown from 1 ml. of fluid medium was 2–4 × 10^8. Such dense fluid culture was suitable for study of the formation of antibiotic-resistant mutants. Our bacterial strain was inhibited by 10 units streptomycin/ml. while the stabilized L-form was sensitive to 0·0001 unit/ml. For antibiotic sensitivity tests, between 100 and 1,000 organisms were used per plate. To obtain mutants resistant to streptomycin we used 4–10-day old cultures of L-forms in charcoal-broth and added an equal volume of charcoal-broth with streptomycin. It was found that the time and frequency of mutation depended on the number of organisms in the culture. When the total number of L-form particles was 10^{11}, organisms resistant to 500 units streptomycin/ml. soon appeared. In 10 per cent of the flasks containing about 10^9 organisms, mutants resistant to 50 units/ml. appeared first, but after 5 days it was possible to isolate mutants insensitive to 500 units/ml. We did not succeed in isolating mutants resistant to 500 units/ml. from populations of only 3–4 × 10^7. Subculturing resistant strains on media with or without streptomycin caused no change in the character of the resistance to antibiotics.

We have also examined the streptomycin sensitivity of unstable L-forms derived from four strains of *Proteus mirabilis* and from their streptomycin-resistant mutants. L-forms obtained from S^R bacteria showed higher resistance than those from S^S organisms. Unstable L-forms derived from streptomycin-resistant bacteria could grow in the presence of 500 units streptomycin/ml., but we noticed that on charcoal-agar containing streptomycin but without penicillin the reversion from L-form to bacterial form was greatly delayed in comparison with that on charcoal-agar without either antibiotic. However, after ten subcultures, the time of reversion became independent of the presence or absence of streptomycin.

L-forms insensitive to 200 units chloramphenicol/ml., obtained by selection, did not show persistent resistance—usually after five or more passages on the medium containing chloramphenicol the culture was completely inhibited.

It was not possible to obtain antibiotic-resistant mutants by ultra-violet irradiation.

Our preliminary investigations suggest that mutants resistant to streptomycin can appear in L-form populations. It has been possible by selection to obtain mutants even more resistant to streptomycin than their corresponding bacterial forms. Probably the highly resistant mutants are formed stepwise rather than as one-step mutants.

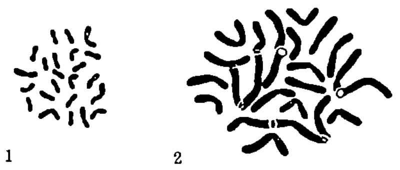
Somatic Chromosomes of *Leptaspis* and *Streptogyna* (Poaceae)

Both *Leptaspis* and *Streptogyna* represent very interesting groups from the point of view of the phylogeny of the Poaceae as their external morphology is very primitive. I collected *Leptaspis cochleata* Thw. and *Streptogyna crinita* Beauv. in woods at Dulva Kanda (about 4,000 ft.) in Ceylon while I was there in 1957. The root tips of the two species were fixed with Navashin solution at the habitats and, after my return to Japan, dehydrated and embedded in paraffin. Sections were cut at 15μ and stained by Newton's gentian violet method. Two individuals of *S. crinita* and one individual of *L. cochleata* were used for chromosome observation. As shown in Figs. 1 and 2, both species had $2n = 24$. The chromosomes of *L. cochleata* are clearly larger than those of *S. crinita*.



Figs. 1 and 2. Somatic chromosomes. (1) *Streptogyna crinita*. (2) *Leptaspis cochleata*. × 2,000

Leptaspis is characterized by the diclinous spikelets and belongs to the Olyreae. The tribe, which has never been examined cytologically, is distributed in the tropics, the majority of species being concentrated in Central America and the West Indies. From anatomical investigations of leaf and embryo, as well as morphological studies, the Olyreae are assumed to be distantly related to the Bambuseae. A number of Bambuseae species examined cytologically up to now have had $2n = 48$ or 72, suggesting the basic chromosome number of 12, whereas a few have $2n = 36$ or 54. *Leptaspis cochleata* is similar to the Bambuseae in the basic chromosome number, but the chromosomes of *Leptaspis* are somewhat larger.

Streptogyna has been referred to an independent tribe, Streptogyneae, by C. E. Hubbard[1]. The genus includes two closely related species which inhabit the tropics. *Streptogyna* had been traditionally treated as a member of the Centotheceae or Festuceae, but the leaf structure of the genus apparently indicates a relationship with the Bambuseae[2]. Streptogyneae and Bambuseae also share some common features in external morphology; for example, in respect to the lodicules the two groups are closely related. Also the chromosomal features of *Streptogyna*, clarified for the first time by the present observation ($b = 12$ and small chromosome sizes), are similar to those of the Bambuseae.

Transformation of a Monochlamydius into a Dichlamydius Chimæra by X-ray Treatment

ACCORDING to Asseyeva[1], X-ray treatment of potatoes is "a powerful and reliable means of transforming monochlamydes into dichlamydes". No details of the treatment used are given in this paper, nor do any appear to have been published in a later paper. It is therefore of some interest to report an X-ray treatment that has given a successful transformation for the potato variety Red King, particularly as similar treatments might also work with periclinal chimæras in plants other than potatoes.

Red King arose as a 'bud sport' in the variety King Edward. It has tubers which are full pink (the pigment is in the periderm, which in potato tubers originates nearly entirely from the epidermis) except for small white patches at the heel end and beneath some of the eyes, whereas King Edward has tubers which are white with pink splashes around the eyes. The occurrence of the small white patches suggests that Red King is a periclinal chimæra in which only layer I has changed, layer II being still King Edward. This is confirmed by the fact that it gives hybrid progenies similar to those from King Edward itself (Table 2), and by the recovery of King Edward type tubers from both eye-excision and X-ray experiments (Table 1).

The results of an X-ray experiment using Red King are given in Table 1. Rose ends of tubers (about 1·5 cm. thick) with small sprouts (about 4 mm. long) were X-rayed by the Department of Radiotherapeutics, University of Cambridge, using a 200-kV. 'Maximar' X-ray machine, run at 15 m.amp. The different dosages were given by exposing them for 6, 7, 8 and 9 min. at 6·75 cm. from the aluminium filter. The highest dosage was lethal to all the sprouts on the treated rose ends. The plants grown from the rose ends receiving lower dosages produced tubers of a number of types, and they included one plant which had tubers of the Red King type but without the small white areas. This is the type to be expected where both layer I and layer II are Red King, and that this was so is confirmed by the breeding results (Table 2)—thus, in contrast to the seedlings from King Edward and normal Red King, the seedlings with coloured tubers in its progeny have full colour and not white with coloured splashes.

Table 1

X-ray dosage (r.)	No. of rose ends treated	No. of rose ends producing plants	No. of plants with tubers of types:					
			Full pink	Red King	Red King plus King Edward	Intermediate Red King–King Edward	King Edward plus white	White
4,500	4	0	—	—	—	—	—	—
4,000	4	3	0	2	0	0	1	0
3,500	4	3	1	0	1	0	0	1
3,000	4	4	0	2	0	1	1	0

Table 2

Parents of cross	No. of plants with tubers of types		
	Full colour	White splashed colour	White
King Edward × white	0	7	12
Red King × white	0	11	19
Full pink from X-rayed Red King × white	5	0	6

The other types of tubers produced by the X-rayed plants have not been studied fully. It should, however, be noted that the plants with white tubers were expected since similar tubers are found in eye-excision experiments with King Edward, Red King and even with white-splashed-colour type seedlings bred from King Edward (ref. 1 and Howard, unpublished work).

Gene Control of Specificity and Activity: Loss by Mutation and Restoration by Complementation

THE *S* gene, controlling the incompatibility reaction between pollen and styles in plants, exists in a very large number of 'alleles', each producing a characteristic antigen in the pollen and a similar antigen with the same specific activity in the style, through which the pollen tube must grow to achieve fertilization. Mutations and recombination of this gene in *Oenothera organensis*, selected out of 10^9 genes, have been of one type only[1]. The chief feature about these mutant *S* alleles is their complete loss of activity in the pollen, so that no active antigen could be detected by the sensitive pollen-style tests. The favoured[2] interpretation was that one part or area of the gene was determining specificity and another area determining a carrier responsible for the activity in pollen and style. The mutant change would then be some defect in the activity-determining area of the gene. With this interpretation it must be concluded that none of the mutants gave an active and changed specificity but only a loss of activity.

The results, however, did not entirely exclude an interpretation based upon two genic areas that determine specificity, one for the pollen and the other for the style. A mutation to a changed specificity in the pollen, unaccompanied by a change in the stylar-determining area of the gene, would be indistinguishable by the tests from a loss of pollen activity. Because of the totally unexpected absence of mutants or recombinants, which results in a changed specificity of pollen and style, when the tests should have revealed them even in low frequency, it was necessary to discriminate between the two interpretations. The experiments designed for this purpose reported here were based upon the comparison of interactions of the mutant with the normal alleles in diploid pollen of artificially produced autotetraploids.

The normal S alleles when in pairs in diploid pollen grains of a tetraploid give a characteristic pattern of the three types of gene interaction—dominance, recessiveness and competition[3,4]. On the two-specificity interpretation of the mutants there are two possibilities: (1) The mutant alleles could have lost the pollen specificity-determining area, in which case there would be no interactions in diploid pollen. (2) The mutant had a changed specificity, in which case the pattern of interactions would be changed. On the one-specificity one-carrier interpretation in which we can postulate only a loss of activity in the pollen for the mutants, there are again two possibilities: (1) There could be a defect or block at a primary stage in gene activity, in which case the mutant allele will show no interactions. (2) The mutant allele might be active in one or more of the early stages of gene action but fails in the later stage to attain final phenotypic expression in the form of the characteristic antigen. If the experiments show that mutant S alleles do not interact in diploid pollen grains, then there is no discrimination between the two interpretations of the structure of the S gene, but on both interpretations this would mean an exclusion of the possibility that the mutations resulted in changed specificity. If, on the other hand, the tests show that the mutant alleles do interact with other alleles, then a discrimination can be made both on the structure of the genes and on the nature of the mutations.

The interactions found with the mutant alleles are compared with those of the original alleles in Table 1. The pattern of interactions is essentially unchanged, thus confirming the one-specificity one-carrier interpretation. But one new and highly significant interaction was found in the pollen grains with S_2 and S_4' alleles. The original allele S_4 is almost completely independent of S_2 in the diploid pollen grain. This was shown by the inhibition of $S_{2,4}$ pollen in styles with either S_2 or S_4 alone and by a stronger inhibition in an $S_{2,4}$ style. The $S_{2,4^1}$ pollen grains are inhibited in S_2 styles, little or not at all in S_4 styles, but the inhibition on $S_{2,4}$ styles is complete and fully as strong as the inhibition of an $S_{2,4}$ pollen grain. Thus the $S_4{}^1$ allele, inactive as it is in a haploid pollen grain, is restored to activity when accompanied by an S_2 allele. The S_2 restores the activity of $S_4{}^1$ not by imposing its own specificity but by allowing $S_4{}^1$ to produce its own original characteristic specificity.

Table 1

	S_2	S_3	S_4	S_6
S_6 (normal)	Strong Comp.	Strong Comp.	S_6 Dom.	-
$S_6{}^1$ (mutant)	Strong Comp.	Comp.	$S_6{}^1$ Dom.	—
S_4 (normal)	Slightly Rec. Indep.	Weak Comp.	--	S_4 Rec.
$S_4{}^1$ (mutant)	Restored to S_4	Weak Comp.	—	$S_4{}^1$ Rec.

Interaction of pairs of alleles in diploid pollen grains to show the comparison between normal and mutant alleles.

Comp., competition; Dom., dominance; Rec., recessiveness; Ind., independent.

This situation is most nearly paralleled by the restorer genes in *Neurospora* which restore the production of the active enzyme tryptophan desmolase in mutants which lack the enzyme. The enzyme appears to be absent in the mutants, but serological tests show that there is a protein present which is serologically identical with the active enzyme[5]. The complementary action of two different alleles to produce glutamic dehydrogenase in *Neurospora* heterocaryons is also similar[6]. The new situation in the S gene restoration is that the restorer is an allele of the restored, that both give products with different specificities and that the restored allele shows its original specificity and not that of the restorer. The origin of new specificities by mutation or recombination still remains a problem.

Analogies between the Compensatory Responses of Fish and Crustacea to Horizontal Displacement of the Body

CERTAIN fish make compensatory swimming movements when they are stimulated by passive displacement of the body or by corresponding displacement of the environment. Experimental analysis shows that this response can be elicited by image displacement on the retina[1], by inertial stimuli[2], by tactile stimuli and by the passage of water over the surface of the fish[3].

In crabs and lobsters a similar set of mechanisms has been shown to exist. Buddenbrock and Friedrich[4], and later Dijkgraaf[5] showed that a rotational stimulus alone would produce compensatory eyestalk movements in crabs similar to those produced by a rotation of the visual field, while Dijkgraaf also showed compensatory responses to tactile stimulation of the legs and to water movement in *Palinurus vulgaris* Latreille[6]. Dijkgraaf proved that the statocyst in the crabs *Carcinus moenas* (L.) and *Maja verrucosa* Milne-Edwards was sensitive to angular displacement, and pointed out the similarity between resulting movements of the eyestalks of crabs and the eyes of vertebrates under similar experimental conditions[5]. However, blind *Palinurus*, though possessing a statocyst, failed to show any rotational sense[7]. On the other hand, Cohen found that when the statocyst of *Homarus americanus* Milne-Edwards was rotated, the discharge-frequency of its nerve underwent a change[8].

Similar experiments have recently been carried out on the behaviour of several species of prawns which confirm that there is a close parallel between mechanisms at work in prawns and crabs and those in fish. In both groups there are several mechanisms that detect displacement of the body; these are present in the same animal and are presumably used simultaneously. In *Palaemon serratus* (Pennant) and *Palaemon elegans* Rathke visual, inertial and tactile stimuli elicit compensatory movements of the eyestalks and to a varying extent of the organs responsible for controlling the direction of movement, that is, the antennæ, pleopods and telson. The statocyst has been shown to be essential to enable these animals to respond to rotation in the absence of visual and tactile stimuli. *Pandalus montagui* Leach, which has no statocyst and which does not respond to inertial stimulation, possesses an additional sense which enables it to respond to water movement when it is rotated; this sense normally augments the response to visual and tactile stimuli.

It is interesting to note that of the four possible mechanisms available to give information about the animal's displacement relative to its environment, no particular crustacean so far studied appears to use more than three to control its direction of movement. *Palinurus vulgaris*, although possessing statocysts, resembles *Pandalus montagui* in giving no response to inertial stimuli, but shows compensatory behaviour when stimulated by water currents, while the other prawns and brachyuran crabs[6] give compensatory eyestalk responses to visual, tactile and inertial stimuli but not to water movements.

The Teleostean Swim-bladder

The enigmatic secretion of gas into the teleostean swim-bladder has been attributed to the acidification of the blood bathing the gas gland epithelium[1]. The resultant local changes of pH, pCO$_2$ and pO$_2$ are thought to be sequestered from the rest of the circulation by counter-current exchange in the rete mirabile. This has been the only credible explanation; but its acceptance has rested upon its credibility. Even though the isolated gas gland epithelium actively converts glucose to lactic acid[2], there has been no evidence, either *in vivo* or *in vitro*, for an oriented hydrogen-ion extrusion into the solution bathing the serosal surface of the epithelium, the surface normally bathed by blood.

The following experiments indicate that the isolated surviving gas gland epithelium of the pollack (*Pollachius virens*, L.) selectively extrudes hydrogen ion into the solution bathing its serosal surface. The gas gland epithelium was dissected free of its serosal coat and exposed to oxygenated saline within 15 min. after removal of the fish from water. The epithelium was mounted as a flat 1-cm.^{2} membrane between simplified chambers[3] that permitted measurement of the trans-membrane potential and membrane conductance. The membrane separated two identical solutions having a volume of 5 ml. and the following composition: sodium chloride 200, potassium chloride 10, calcium chloride 5, magnesium chloride 2, glucose 25 and yohimbine 0·002 mM/l. The solutions were gassed with 100 per cent oxygen and experiments were conducted at an ambient temperature, 22° ± 1·6° C., which was probably supraoptimal. The bathing solutions were removed at 2-hr. intervals and the initial pH recorded after 15 min. of gassing with air passed through a soda-lime column. Using a glass and calomel electrode pair stable and linear within pH 0·05, the solutions were titrated to pH 7·0 with 12 mM sodium hydroxide.

The gas gland epithelia from five fish were observed for two successive 2-hr. periods. The rate of extrusion of hydrogen ions into the bathing solutions, mean and standard deviation of 10 observations, expressed as µequiv. cm.$^{-2}$ hr.$^{-1}$ was 0·53 ± 0·3 into the serosal and 0·08 ± 0·07 into the lumenal solution. The corresponding pH of these solutions was 4·8 ± 0·2 and 6·2 ± 0·8, respectively. The wet weight was 67 ± 37 mgm. Neither the amounts of hydrogen ion extruded nor the resultant hydrogen ion concentrations suggest that these observations were the result of a casual autolytic phenomenon. In my experience the rate of production of lactate by the frog gastric mucosa is 0·08 µequiv./105 mgm. wet weight/hr. It should be noted that the acidification of the solutions bathing the gas gland epithelium does not result from hydrogen ion transport from one solution to the other, as is the case for the gastric mucosa with an equivalent alkalinization of the serosal solution during acidification of the lumenal solution[4]. While no attempt was made to identify the metabolic acid generated by the gas gland epithelium, the titration curves suggest that extrusion of hydrogen ions was associated with a weak electrolyte the pK of which was considerably higher than that of lactic acid. In all experiments there was no significant trans-epithelial potential difference. It was less than 1 mV. The d.c. conductance was 7·2 mmhos. cm.$^{-2}$.

The rate of secretion of hydrogen ions by two gastric mucosae of the pollack was also determined for comparison. When the serosal surface of these mucosae was bathed by a somewhat different solution containing sodium bicarbonate 30, sodium hydrogen phosplate 1 and histamine 0·1 mM/l., and both solutions gassed by 95 per cent oxygen and 5 per cent carbon dioxide, the mean rate of hydrogen ion secretion was 1·5 µequiv. cm.$^{-2}$ hr.$^{-1}$, the pH of the lumenal solution 4·2, wet weight 155 mgm. and conductance 7·8 mmhos. cm.$^{-2}$. As expected, there was a significant gastric trans-mucosal potential of 10–20 mV.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Monday, December 8

Royal Geographical Society (at 1 Kensington Gore, London, W.7), at 6 p.m.—"Journey Into Spring" and "Between the Tides" olour Films).

Tuesday, December 9

Physical Society, Low Temperature Group (at the Institute f Physics, 47 Belgrave Square, London, S.W.1), at 9.30 a.m.—iscussion Symposium on "Low Temperature Heat Exchangers".

Society of Chemical Industry, Agriculture Group (at 14 elgrave Square, London, S.W.1), at 10.30 a.m.—Forestry Meeting.

Institution of Mechanical Engineers, Automobile Division t 1 Birdcage Walk, Westminster, London, S.W.1), at 4 p.m.—Three apers on "The Dynamics of the Internal Combustion Engine".

Zoological Society of London (at the Zoological Gardens, egent's Park, London, N.W.1), at 5 p.m.—Scientific Papers.

Parliamentary and Scientific Committee, General Com-ttee (in Committee Room 12, House of Commons, London, S.W.1), 5.15 p.m.—Dr. E. E. Pochin and Prof. B. W. Windeyer: "The edical Problems of Living in the Nuclear Age".

Institution of the Rubber Industry, London Section (at the oyal Society of Tropical Medicine and Hygiene, Manson House, 6 Portland Place, London, W.1), at 5.30 p.m.—Mr. J. Ames: "Com-ounding and Vulcanisation of Silicone Rubber". 7 p.m.—Mr. C. G. ynch: "Practical Safety in the Rubber Industry".

University of London (at Imperial College of Science and Techno-gy, London, S.W.7), at 5.30 p.m.—Prof. D. B. Spalding: "Heat ransfer in Rocket Motors".

Iron and Steel Institute (in the Weir Lecture Hall of the Institu-ion of Naval Architects, 10 Upper Belgrave Street, London, S.W.1), t 6 p.m.—Dr. N. P. Allen, F.R.S.: "The Mechanical Properties of the errite Crystal" (Eleventh Hatfield Memorial Lecture).

Society of Chemical Industry, Chemical Engineering Group t 14 Belgrave Square, London, S.W.1), at 6 p.m.—Dr. R. Roberts: Some Aspects of Radiation Induced Chemical Processes".

Institution of Electrical Engineers, London Graduate and tudent Section (at Savoy Place, London, W.C.2), at 6.30 p.m.—r. H. E. Coles: "The Application of Electronics to Jet Engine ontrol".

Society for Analytical Chemistry, Biological Methods Group t "The Feathers", Tudor Street, London, E.C.4), at 6.30 p.m. —Fourteenth Annual General Meeting, followed by a Discussion eeting on "Methodological Reminiscences" opened by Dr. S. K. Kon.

Royal Aeronautical Society (in the Theatre, Park Lane House, 45 Park Lane, London, W.1), at 7 p.m.—Mr. S. S. Hall and Mr. A. homas: "Application of a Constant Frequency A.C. Electrical ystem to Aircraft and Missiles".

Royal Aeronautical Society, Graduates' and Students' ection (at 4 Hamilton Place, London, W.1), at 7.30 p.m.—Mr. E. C. owyer: "The Future of the British Aircraft Industry".

Wednesday, December 10

Iron and Steel Institute (at Caxton Hall, Caxton Street, London, .W.1), at 10 a.m.—Autumn General Meeting. Formal Business: lection of Members. Followed by technical sessions at Caxton Hall nd also at the Institution of Naval Architects, 10 Upper Belgrave treet, London, S.W.1.

Physical Society, Colour Group (in Room 102, Northampton ollege of Advanced Technology, St. John Street, London, E.C.1) t 3.30 p.m.—Mr. F. H. Ludlam, Mr. P. Saunders and Dr. J. Hallett: Some Colour Phenomena in Meteorology".

Geological Society of London (at Burlington House, Piccadilly, ondon, W.1), at 5 p.m.—Dr. C. B. Crampton: "Fabric Analysis f Moine and Cambrian Quartzites of the North-West Highlands of cotland" (paper communicated by Dr. F. Coles Phillips).

Eugenics Society (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Dr. J. A. Fraser: "Human enetics at Two International Conferences".*

Society of Instrument Technology, Control Section (at anson House, Portland Place, London, W.1), at 6 p.m.—Mr. H. Gill: An Experimental Approach to some Control Problems of Multi-tand Rolling Mills".

Society for Analytical Chemistry, Microchemistry Group in the restaurant room of "The Feathers", Tudor Street, London, .C.4), at 6.30 p.m.—Discussion Meeting on "The Use of the Micro-cope in Analysis" opened by Mr. R. L. Causer.

Wednesday, December 10—Friday, December 12

European Association of Exploration Geophysicists (at the nstitution of Civil Engineers, Great George Street, London, S.W.1)—Vinter Meeting, opened by Sir Vivian Fuchs.

Thursday, December 11

Iron and Steel Institute, Iron and Steel Engineers Group at Caxton Hall, Caxton Street, London, S.W.1), at 10 a.m.—Meeting n "Vacuum Processes in the Iron and Steel Industry".

Sir Thomas Middleton Memorial Trust (in the Auditorium, The Wellcome Building, 183 Euston Road, London, N.W.1), at 5.30 p.m.—Dr. John R. Raeburn: "Economic Aspects of Uncertainties in British Agriculture" (Sixth Middleton Memorial Lecture).

Institution of Mechanical Engineers (joint meeting with the Institution of Electrical Engineers, at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. C. M. Cock: "The 'Deltic' Locomotive".

Institution of Mechanical Engineers, Industrial Administration and Engineering Production Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "The Engineer in Production—His Training and Utilization".

Chemical Society (at Burlington House, Piccadilly, London, W.1), at 7.30 p.m.—Prof. G. Porter: "The Triplet State in Chemistry" (Tilden Lecture).

Royal Society of Tropical Medicine and Hygiene (at Manson House, 26 Portland Place, London, W.1), at 7.30 p.m.—Prof. P. C. C. Garnham and Dr. D. J. Lewis: "Parasites of British Honduras with special reference to Leishmaniasis".

Friday, December 12

Biochemical Society (in the Department of Biochemistry and Chemistry, The Medical College of St. Bartholomew's Hospital, Charterhouse Square, London, E.C.1), at 2 p.m.—378th Meeting.

Institution of Electrical Engineers, Education Discussion Circle (at Savoy Place, London, W.C.2), at 6 p.m.—Discussion on "The Teaching of Mathematics to Engineers" opened by Mr. M. Bridger.

Royal Institute of Chemistry, London Section (at Northampton College of Advanced Technology, St. John Street, London, E.C.1), at 7 p.m.—Dr. J. K. Aiken: "The Application of Sequestering Agents".

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Dr. T. E. Allibone, F.R.S.: "The Fusion of Heavy Hydrogen".

Saturday, December 13

London County Council (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3.30 p.m.—Mr. J. C. Jewell: "Exploration of the Andes".*

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Laboratory Technician (with either experience in laboratory, work, preferably in tissue culture, or the G.C.E. (Advanced) in two mathematical or scientific subjects) in the Tissue Culture Unit dealing with the production of kidney-cell cultures for growth of viruses—The Secretary, Research Institute (Animal Virus Diseases), Pirbright, Surrey (December 10).

Lecturer in Organic Chemistry at Birkenhead Technical College —The Director of Education, Birkenhead Education Committee, 63 Hamilton Square, Birkenhead (December 10).

Demonstrator or Tutorial Student in the Department of Chemistry—The Registrar, University College of North Staffordshire, Keele, Staffs (December 13).

Mathematicians (with a first- or second-class honours degree or equivalent in mathematics or physics) in the Health and Safety Branch of the Atomic Energy Authority, to join a section concerned with assessment of safety from criticality hazards in the handling and processing of fissile materials and theoretical research into the factors governing criticality and the effects of super-criticality—The Recruitment Officer, United Kingdom Atomic Energy Authority, Industrial Group Headquarters, Risley, Warrington, Lancs, quoting Ref. 2768/T (December 15).

Experimental Psychologist to join the Behavioural Research Unit—The Registrar, The University, Sheffield (December 16).

Joseph Lucas Research Student (with a good honours degree in mechanical or electrical engineering or physics, and preferably some research experience), for research into the initiation of explosions in gases, vapours and powder clouds; and a Joseph Lucas Research Student (with a good honours degree in some branch of engineering, physics or chemistry), for research into the mixing of powdered materials—The Registrar, King's College (University of London), Strand, London, W.C.2 (December 17).

Usines Emile Henricot S.A. Research Student (with a good honours degree in some branch of engineering), for research into various aspects of the mechanical behaviour of ball mills—The Registrar, King's College (University of London), Strand, London, W.C.2 (December 17).

Assistant, Grade B (qualified to teach physics, and preferably the ability to teach applied physics), in the Science Department, Croydon Technical College, Fairfield, Croydon—The Chief Education Officer, County Borough of Croydon Education Committee, Education Office, Katharine Street, Croydon, Surrey (December 20).

Postdoctoral Fellow (with a Ph.D. or equivalent qualification) in the Department of Physical and Inorganic Chemistry, to carry out fundamental work on gas-phase chromatography—Prof. D. H. Everett, Department of Physical and Inorganic Chemistry, The University, Bristol 8 (December 20).

Demonstrator (Assistant Lecturer) in Physiology—The Registrar, The University, Leeds 2 (December 29).

Lecturer (with a knowledge of the meat industry or microbiological experience which can be applied to problems of food hygiene) in Applied Veterinary Pathology—The Registrar, The University, Liverpool (December 30).

Assistant Lecturer (medically qualified) in Physiology—The Registrar, The University, Sheffield (December 31).

Senior Demonstrator in Inorganic and Physical Chemistry; and a Research Fellow in Chemistry—The Registrar, The University of Melbourne, Carlton, N.3, Victoria, Australia (December 31).

Chair of Nuclear Engineering—The Registrar, The University, Manchester (January 1).

Senior Lecturer in either Inorganic and Physical Chemistry or in Theoretical Chemistry—The Clerk to the Governors, Woolwich Polytechnic, London, S.E.18 (January 1).

Scientific Officer or Senior Scientific Officer (with a Ph.D. in astronomy or allied subject; or appropriate science degree (first- or second-class honours) with at least three years relevant (for example, postgraduate) experience, and preferably a knowledge of celestial mechanics) at the Royal Observatory, Cape Town—The Civil Service Commission, 30 Old Burlington Street, London, W.1, quoting Ref. S.4910/59 (January 8).

Lecturer (Grade II) in Inorganic Chemistry—The Registrar, The University, Bristol (January 10).

Chair of Psychology in the University of Adelaide, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, January 12).

Chair of Philosophy in the University of Western Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, January 30).

Chair of Geography—The Registrar, The University, Sheffield (January 31).

Lecturer in Botany at the University of Otago, Dunedin, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand, January 31).

Experimental Officer (at least 26, with a general science degree with G.C.E. in mathematics at advanced level) in the Research Branch of Headquarters, Royal Air Force Bomber Command, for work in the computer section (mainly programming and operating electronic computers)—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting Ref. A.427/8A.

Laboratory Technician (male or female, experienced in biology and interested in animals)—The Secretary, Furzedown College, Welham Road, London, S.W.17.

Lecturer, Grade IIa (with a first- or second-class honours degree) in Physics—The Principal, Paisley Technical College, 28–40 George Street, Paisley.

Lecturer (with good academic qualifications and industrial experience, preferably in the food industry) in Applied Microbiology—The Secretary-Treasurer, Royal College of Science and Technology, Glasgow, C.1.

Physicist (with a first- or second-class honours degree in physics), to undertake original research in the field of mechanical properties of high polymers—The Secretary, British Rayon Research Association, Heald Green Laboratories, Wythenshawe, Manchester 22, quoting Ref. P.5.

Professor of Communications Engineering at the Indian Institute of Technology, Kharagpur, India—The Ministry of Labour and National Service (E.9), 26–28 King Street, London, S.W.1, quoting A.12/IND/244/TCS.

Senior Physicist (with first-class professional qualifications, substantial experience of work with radioisotopes or ionizing radiations and the organizational ability to manage a department) at the Radiochemical Centre, Amersham, to take charge of the Physics Department—The Group Recruitment Officer (1267/34), Atomic Energy Research Establishment, Harwell, Didcot, Berks.

Senior Research Officer or Research Officer (mathematical statistician with a good academic record), to undertake research, to lecture and to teach statistics at undergraduate and postgraduate levels—The Secretary, Institute of Statistics, The University, St. Cross Road, Oxford.

The standard of all time—!

AN INTRODUCTION TO THE THEORY OF STATISTICS

G. UDNY YULE, M.A., F.R.S.,
M. G. KENDALL, Sc.D.

This well-known text, revised by Professor M. G. Kendall, is designed for students of the many sciences in which statistical methods are employed. Providing a complete introductory course in statistics, the book includes some important tables for reference. Many worked examples are given, and numerous exercises for the student to solve for himself—with hints and answers at the end of the book.

In my opinion, this is the best book on statistics that was ever written.—J. Neyman in *Nature*

There is no other book so inspiring to the young research worker—*J. Roy. Stat. Soc.*

FOURTEENTH EDN., Third imp. 1958. 701 pages. 45s. net.

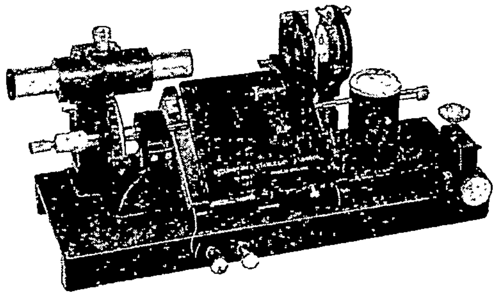
PRECISION B&S INSTRUMENTS

Fabry-Perot Interferometer



Although of very simple design, this instrument is suitable for much of the work usually carried out by more elaborate and costly apparatus, and reads directly to 1/250 mm. It can be supplied with an attachment to convert to a Michelson interferometer, thus giving a dual purpose instrument.

Price Complete	£190 0s.
Attachment for converting instrument into Michelson Interferometer, extra	£45 0s.
Polished wooden case, extra	£9 10s.

THE FUNCTION OF UNIVERSITIES

IN an article on "Science and the Nation" in the October issue of *Foreign Affairs*, which reflects something of the outlook of his recent presidential report to the Carnegie Institution of Washington, Dr. Caryl Haskins points out that science is now an important element in general culture. Those training professionally for science and technology must accordingly become familiar with the context of the political world if they are to be capable of meeting the responsibilities that are likely to fall upon them. The rate and success of technical progress, Dr. Haskins emphasizes, is a function of a country's organizing capacity and application, and of the suitability of the chosen modes for development and of its tradition ; but it is also a function of the common heritage of the whole body of learning.

Dr. Haskins was addressing an American public, with the situation and needs of the United States primarily in his mind ; but much that he said is just as applicable to Great Britain. It is, for example, no less true in Great Britain than in the United States that the modes by which knowledge and insights of the natural world are obtained and most effectively assimilated, and especially the creation of new knowledge, are highly human factors, conditioned by the basic assumptions of each society ; and in both countries it is necessary to be on guard against blindly seeking to adopt modes which succeed elsewhere without forethought or regard to those conditions and assumptions. To-day none of the larger problems will be amenable to clear and final solutions. Rather, they will present prolonged tests of persistent and concentrated purpose. Except in war, processes of social change and growth in dynamic systems are continuous and involve every part and aspect of the whole of society.

Like many others, Dr. Haskins points to the necessary condition for creativeness in a free society, namely, wide and unimpeded horizons and the total freedom of the individual ; but he goes on to bring out the corollary, in such a society as he is depicting, of the increased social importance of intellectual attainment and of the urgent need to foster and expand the means to seek and cultivate intellectual powers. That is indeed the key-note of his article. What he writes further about the dual nature of science itself and the significance of the effective partnership of profound philosophy and practical experiment represented by modern science, on the proper use and cultivation of scientific man-power, and on the need for deeper study of the problems of management and communication, is both sound and important but really secondary to the main theme.

It is against this background that the pregnant chapter on educational problems in the recent report entitled "University Development"* from the University Grants Committee is most appropriately considered. "In our view," writes the University Grants Committee, "the first duty of the university to the student is to teach him how to think." The note is in harmony with that struck by Dr. Haskins, and both are sounded in a world where, despite its growing dependence on intellectual effort, there appears to be both a disturbing amount of illiteracy and a growing distrust of, or even opposition to, the intellectual.

That context gives an urgency to the whole problem which sharpens the wise words of the University Grants Committee. We in Britain have neither time nor man-power to spare, and we must do the best we can for the great bulk of our students within the limits of the three-year undergraduate course. Moreover, as the Committee points out trenchantly, if the university fails to teach the student to think, he is not very likely to learn to do so afterwards, and his capacity for development will be limited.

The great value of this chapter is that, as is done in so many earlier reports from the University Grants Committee, the problem is set in its true perspective, and the relative importance of the various factors appears. We see why the student needs not only competence in one field of knowledge but also access to related fields and a general appreciation of the art of learning. The contribution which different sources can make appears, as does the significance of the change in the social and economic background of students. Moreover, in a passage closely parallel with what Dr. Haskins has written, the Committee analyses the qualities of mind which distinguish a person of education and indicates precisely why a student needs to be shown that intellectual pursuits are enjoyable for their own sake, and to be given the sense of being in touch with creative work in which, if he does well, he may later be privileged to participate. Nor are we allowed to overlook the way in which the teacher can do this.

Here we are carried back to a preceding chapter of the report, for if the vital part is that played by the teacher, it is essential to attract teachers of the highest quality. Not only, however, are university lecturers rarely trained teachers ; what is more serious is that teaching is frequently regarded as an irritating interruption of the research which they consider to be their primary function, though it must be remembered that there are still those, like Dr. A. L. Goodhart in his Haldane Memorial Lecture of 1952, who maintain strenuously that a university is primarily a teaching institution. The University Grants Committee reiterates its conviction that the two functions of research and teaching are too intermingled for discussion of their relative importance to be fruitful ; nevertheless, teaching is unlikely to acquire the prestige and status the Committee regards as proper until universities cease to appoint, and promote, almost exclusively upon the evidence of papers published in the journals of learned societies.

More than this may well be required to make even university teaching attractive to as many of the ablest minds of each succession of graduates, but this is an essential condition of solving one limited aspect of the major problem of communication. A keener interest in teaching itself, however, is likewise a prerequisite of the concerted action on the part of schools, colleges and universities which the University Grants Committee urges in order to overcome the difficult problems of entrance requirements where they impinge on the question of general education. Moreover, if the amount of information which the student is required to absorb during his first-year course is to be reduced and the time saved used in preparing him for life in more important ways, teachers, rather than administrators, have a part to play, constructive and not merely negative. Merely from this point of view, the proposal under discussion at Cambridge for teaching the principles of science to men coming mostly from the humanities is welcome evidence of the stirring of minds among university teachers. Success will depend on vision as well as on constructive thought, and on the cumulative effect of a number of comparatively small changes, all inspired by a definite purpose and by a clear conception of what the university should try to do with the students entrusted to its care.

---

* University Grants Committee. University Development 1952–1957. Pp. 92+8 plates. (Cmnd. 534.) (London: H.M. Stationery Office, 1958.) 5*s*. 6*d*. net. See also *Nature*, November 1, p. 1199.

Some, but by no means all, of these opportunities are noted by the University Grants Committee. There is the matter of technicians and of other assistants, the scarcity of whom is responsible for much waste of highly trained scientific man-power in academic research. Some improvement in this respect could have other advantages as well as the reduction of this kind of waste: it might well make teaching duties less repugnant to the younger staff in particular, because they would be able to make more effective use of the time at their disposal for research, and teaching would not be regarded as so serious a distraction from original work. Moreover, administrative duties could sometimes be considerably reduced by a reasonable provision of typing facilities. Indeed, the more evident it becomes that, whether we regard the university from the point of view of staff or student, we are dealing with a strictly limited national resource which is both indispensable and irreplaceable, the greater the care that should be taken to see that highly trained man-power is not wasted on duties that do not require its exercise, and that university places and privileges are not offered to those unlikely to benefit by them.

More positively, however, if teaching is to regain the prestige it enjoyed when Jowett's view was fashionable—that education is the first and final function of a tutor and that the pupil and not research must come first—something more than negatives is required. Fortunately, the very field of communication itself is opening up new possibilities, and while we are required to think out anew the content of many courses in the light of the immense expansion of knowledge and the contracting amount of time available, new techniques are available to assist in resolving some of our problems. The task of communication, even of inter-communication, has its own attractions, and in solving some of its complex problems, we may well find help in solving the parallel problem of general education.

One of the auxiliary factors to which the University Grants Committee gives more than a passing glance is the university library; and here it may be said that this factor is as essential in science and technology as in the humanities or the social sciences. The standard of library provision profoundly affects the effectiveness of teaching generally, and although it does determine the practicability of research in science, as it may well do in the humanities or in the social sciences, it may have repercussions on the extent of scientific research. Inadequate provision of scientific periodicals or major and highly expensive reference books can cause serious delay, and may even lead to waste or duplication of effort.

Apart, however, from its bearing on the waste of skilled man-power and on the attractiveness and efficiency of teaching in some fields, the quality of library provision can bear on yet another factor. Ten years ago, urging the need for more thinking about the importance of existing knowledge, Sir Walter Moberly suggested that we need more books which throw new light on the significance and interrelations of old facts, and that the universities should encourage and honour not only discoverers of facts hitherto unknown but also explorers of ideas and re-thinkers of values. An adequate library is an essential adjunct in the kind of creative thought and writing which Sir Walter had in mind, and this is not the least important of the reasons why library expansion needs to proceed *pari passu* with university expansion, and probably rather faster than it has been doing generally over the past decade. It is also an added reason for welcoming the study of function and design in this field which the Nuffield Foundation is fostering.

Nor is this unrelated to the prime purpose of a university and to the establishment of teaching in its proper status in both external and internal regard. When the universities are recognized as effectively fulfilling this function of supplying the large numbers of well-educated men and women needed, whatever their special field of work, the university teacher would be assured of a position in the public esteem which will attract to that calling a sufficient supply of our ablest young men and women. Public opinion alone can dispose of any tendency to discredit the occupation of university teacher, but the university teacher himself can do something to encourage public understanding.

It may be given to only a few to produce books of the calibre suggested by Sir Walter Moberly; but the contribution of such books to public understanding of the work of the universities is not negligible. Many more, however, may find an opportunity of participating in the regional work of the university and in adult education, and through both of these a direct impact is made on the public. In this way a decisive contribution could well be made to the formation of a better-educated community, on the very existence of which the free world to-day depends. There are, of course, strict limits to what is possible in such fields. First things must come first, and neither the university nor the individual teacher should be deflected from work of university standard. It is only with a very clear idea of what is the place of the university in the modern world, and what it should seek to bring to its students, that either the university as an organized body or the individual teacher should accept extra-mural duties or responsibilities.

Nevertheless, without accepting some such duties or responsibilities and keeping them in balance with other and primary responsibilities, the universities can scarcely hope to fulfil their function in the world to-day. They need such external co-operation in shaping their own methods to the needs of to-day. Increasingly they depend on public understanding for the financial support required to make their teaching adequate and their research effective. As was resolved at the regional European seminar on the "Universities and Adult Education" at Bangor in September 1956*, arranged by the United Kingdom National Commission for the United Nations Educational, Scientific and Cultural Organization, in the rapidly changing world of to-day adult education in all its many forms is more than ever necessary to help men and women in making the many adjustments which rapid change requires ; it is essential to the development of their individual powers of understanding, judgment and enjoyment, and for providing society with well-informed and thoughtful leaders for all sectors of industrial, social and civic organization.

The universities in Great Britain, or in any other country, cannot be indifferent to enterprises of such profound social importance. How that assistance is best given will vary widely from country to country, even from university to university, and its extent can only be decided in relation to a university's resources and other responsibilities. That urgent and intensive thought should be given to the nature, the magnitude and the technique of the universities' contribution in this field even in this time of expansion and stress is undeniable ; nor should it be forgotten that the response of the universities to this call may not only have valuable effects in promoting public understanding and support of their primary work but also may in turn lead to fresh light being thrown on some of their own difficult problems in general education and courses and the like. Education must be regarded as a whole. However admirably the universities may fulfil their function of providing society with trained, informed and inquiring minds, capable of clear thinking and balanced judgment, those minds will only be able to work effectively in the framework of a society that has some understanding and appreciation of the nature of their capabilities, and is prepared to allocate the resources essential for the universities to continue their work. Adult education and regional work from one point of view are part of the work of promoting effective public relations, which the growing dependence of the universities on public support makes more and more necessary.

THE HISTORY OF A DECIPHERMENT

The Decipherment of Linear B

By John Chadwick. Pp. xii+147+2 plates. (Cambridge: At the University Press, 1958.) 18*s*. 6*d*. net.

NOT the least interesting side of Michael Ventris's genius was his willingness to think aloud, and to make mistakes in public. In the two years of intensive work which ended in June 1952 with the decipherment of the so-called Linear B tablets, he prepared and circulated twenty 'work notes', totalling 176 foolscap pages. "All the rough working," Chadwick points out, "all the mistakes are exposed to view." In 1940, Ventris, then eighteen years old, had published an article suggesting that Etruscan was the language most likely to provide the clues to the decipherment of Linear B ; and this idea held him in thrall until the last moment, when, almost against his will, the work itself drove him to the correct, and decisive, conclusion that the language of the tablets was Greek.

We thus have an interesting case study in the triumph of sound method over prejudice and presuppositions. For a generation or more attempts to decipher Linear B had made no progress whatsoever simply because no one thought to apply the well-established principles of cryptography. Instead, reputable scholars and cranks alike did nothing more sensible than make guesses, a number of which were published, even by the most eminent of university presses, despite the fact that any intelligent reader could have exposed the 'results' with ease. Why this situation should have prevailed so long and without significant exceptions, until two Americans, Alice Kober and E. L. Bennett, finally began the obvious work of cryptographic analysis, is a mystery, though perhaps no more so than many similar blind spots in the history of science. Ventris built on their work and brought it to a rapid and successful conclusion. Because he clung for so long to his Etruscan theory, and because he did his thinking out loud, the work notes and related documents provide the raw material for a valuable contribution to the history of scientific discovery ; to its psychology, I might say. It is not often that not merely the operations but also the day-to-day thinking behind them, behind the false starts and mis-steps as well as the successes, are recorded so freely.

In a way, therefore, it is a pity that Chadwick, who was Ventris's close collaborator from June 1952, chose to write another kind of book. This little work is a reliable popular presentation of the Mycenæan tablets, their discovery, decipherment, and contents. (Readers of *Nature* will find an admirable summary by R. M. Cook in a review of another work on pp. 152–53 of the issue of July 19, 1958.) Only Chapter 4 offers a little of the material from the work notes and voluminous correspondence, enough to correct some of the misapprehensions about Ventris's methods current even in some professional circles (specifically among the few scholars who still refuse to accept the validity of the decipherment), probably enough to satisfy most lay readers, but far from enough for the permanent record which ought to be made. It can be argued that the disproportionately long chapter entitled "The Decipherment and its Critics" is unnecessary. Neither Beattie in Edinburgh nor

Grumach in Berlin will be convinced by these twenty pages, and for the rest of us the test of the decipherment is in the further work based upon it, not in the endless repetition of the sterile quarrel which has been carried on for nearly five years in both learned journals and the Sunday newspapers. Much more would have been gained by devoting these twenty pages to further exploration of the actual work of decipherment.

The final chapter, "Life in Mycenæan Society", though it has little of the air of polemic about it, is a deceptively valuable contribution to a still vigorous debate. Indiscipline and romantic guesswork did not come to a sudden end with Ventris's decipherment: they merely moved from decipherment to interpretation. Enthusiasm far outran the evidence, which is severely limited by both the incompleteness of the decipherment (only six years old, after all) and the very restricted contents of the tablets. Inevitably, the layman's knowledge comes from the popular presentations, and they have tended to exaggerate what we know, sometimes quite wildly. It is therefore useful to have the weight of Chadwick's authority, in a popular work, placed in the scales on the side of caution and of frank recognition of how little we still know about Mycenæan society.

M. I. FINLEY

WESSEX LONG AGO

Wessex Before the Celts

By Dr. J. F. S. Stone. (Ancient Peoples and Places, Vol. 9.) Pp. 207 (72 plates). (London: Thames and Hudson, Ltd., 1958.) 25*s*. net.

NOBODY who knew the late Dr. J. F. S. Stone can read this book, "Wessex", without much sorrow at his sudden and untimely death. Indeed, the work has only been finally completed and passed for press thanks to the kindness of Prof. Stuart Piggott.

The book covers a considerable area of ground and deals with a long period of time—the Mesolithic epoch until the arrival of the Celtic folk. There are 148 pages of text, a reasonable bibliography and 38 pages of illustrations. Nowadays in Great Britain there are a large number of amateurs interested in archaeology, and this book, like the others in the series, is designed for them. The space available is barely sufficient to give a general picture of the Wessex scene during the various periods and specialists must not expect any detailed accounts. The Palæolithic period is omitted, and the work starts with a few words on the Mesolithic (forest) cultures as a background to a rather fuller account of the first Neolithic inhabitants. There follow a few pages devoted to the various barrows of these times, and the flint mines whence came the raw material for tool making. The later Neolithic invasions and the coming of the Beaker folk are next considered in greater detail, and these lead on naturally to an excellent account of Stonehenge, Avebury, etc. A couple of chapters on Bronze Age times carry the story on to the epilogue, "Celtic Wessex". The book as a whole is a good example of its kind and can be recommended without reserve for those readers, non-specialist but interested generally in the past, for whom it was composed.

M. C. BURKITT

THE INDIAN AGRICULTURAL SERVICE

Agricultural Research in India

Institutes and Organisations. By Dr. M. S. Ranc
hawa. Pp. v+448+79 plates. (New Delhi: India
Council of Agricultural Research, 1958.) Rs. 20
40*s*.; 6 dollars.

THREE facts will suffice to make the importanc
of agricultural research to India abundantl
clear: (1) that three-quarters of the populatio
depend directly on agriculture for a living; (2) tha
the need for national action to improve agricultu
was first officially stated by committees set up i
1880, 1888 and 1901 with the ominous name (
Famine Commissions; and (3) that each year no
food has to be grown for 5,000,000 additional peopl
so that only to maintain present standards of nutritic
demands a steady and continuous rise in productio

This handsome volume, prepared by the Vic
President of the Indian Council of Agricultur
Research, shows how much the Indian Governmen
is spending and how it organizes research in i
attempts to get the knowledge that will be neede
before the fear of famine can be banished and tl
living standards of the bulk of the population i
creased. The book is less one for reading than f
reference, with its main value to find out whe
different crops and problems are being studied, wh
is working on them, and what body is responsible f
finance, administration and for co-ordinating wo
done in the different States. Nevertheless, tl
descriptions of the work at the various institutes a
detailed enough to show that, despite the very man
problems still waiting a solution, much has bee
found out that could improve yields by the bett
feeding of crops and livestock, by the control of pes
and diseases, by irrigation and by the growing (
higher-yielding varieties. The book deals only wit
research, and some information about the importa
and difficult problem of getting discoveries applie
would have added to its value.

It is necessary only to turn the pages to be ir
pressed by the growth in agricultural research, fro
its beginnings in 1905 at the Imperial Agricultur
Research Institute, Pusa, Bihar, which was destroy
by the earthquake of 1935, to the present nine centr
research institutes, several commodity research i
stitutes and the more than thirty research statio
and farms in the different States. The photograp
leave no doubt that many large and magnifice
laboratories have been built, but provide litt
evidence on the standard of the physical equipmen
However, staff is the most important equipment (
any research establishment, and here also the numbe
are impressive, at least at first sight. The India
Agricultural Research Institute, the new Pusa base
on Delhi, with about 350 graduates, is probab
much the largest in the whole Commonwealth, ar
some of the others are also of considerable size. Eve
so, India is so vast and conditions so varied tha
many more could undoubtedly be justified, for as
proportion of the population engaged in agricultu
the number is much below that in many oth
countries. But quantity of staff is less importa
than quality; although government may provi
new buildings, physical equipment, organizing cor
mittees and lakhs of rupees for salaries, only tl
research workers can produce results. It is r
exaggeration to say that the prosperity of Ind

may depend on the outcome of the efforts of those whose names are listed at the end of this book, and all will surely join in wishing them every success in their vitally important work. F. C. Bawden

AERONOMY

The Upper Atmosphere

By Prof. H. S. W. Massey and Dr. R. L. F. Boyd. Pp. xii+333+28 plates. (London: Hutchinson and Co. (Publishers), Ltd., 1958.) 63*s*. net.

THE science of the upper region of the terrestrial atmosphere, where dissociation and ionization are important, has many facets. Because of the various interrelations that exist, none of these can be treated properly in isolation. Yet few people have the time and ability to become experts in the whole of this rapidly expanding science (which has been given the name 'aeronomy', following a suggestion by Prof. Sydney Chapman). For some years past there has been a need for an up-to-date book giving a survey of the entire field in simple terms so that a specialist in any one branch can readily obtain at least a general understanding of the work being done in other branches; for example, so that a radio man may learn something of the nightglow without bothering himself with the notation of molecular spectra, and so that a photochemist may learn something of the theory of the diurnal variations in the geomagnetic field without mastering the mathematics involved. There has also been a need for an elementary text which can be recommended to post-graduate students. Prof. Massey and Dr. Boyd do much to meet these needs by their admirable new book, "The Upper Atmosphere", though, regrettably, they do not include any references to the original literature.

The first two chapters are introductory in character. One of them recalls the basic principles of the relevant physics in elementary sections on electricity and magnetism, on wave motion of various types and on atoms and molecules; the other gives a short review of the main properties and phenomena of the upper atmosphere, anticipating the later, more detailed accounts.

These are followed by three chapters on the principal types of probe used—sound, radio and material. The chapter on material probes is particularly valuable in that it contains much information on balloons and rockets which has never been collected together before. Towards the end of the book there is a related chapter on artificial satellites, giving an interesting discussion of some of the important investigations which may be carried out with their aid.

The remaining chapters cover the following: the chemisphere and the ionosphere; the night-glow and the aurora; aerial tides and magnetic effects; solar, magnetic and ionospheric disturbances; meteors; cosmic rays. As would be expected, the exposition is lucid.

In addition to the six plates in colour and the twenty-two plates in black and white, there are a large number of instructive line drawings, many of them specially prepared. An excellent index adds considerably to the usefulness of the book, which should be in the library of every serious research worker in any branch of aeronomy.

D. R. Bates

DIOPHANTINE ANALYSIS

An Introduction to Diophantine Approximation

By Dr. J. W. S. Cassels. (Cambridge Tracts in Mathematics and Mathematical Physics.) Pp. x+166. (Cambridge: At the University Press, 1957.) 22*s*. 6*d*. net.

THE approximation to an irrational θ by rationals p/q depends on the distance between $q\theta$ and the nearest integer, a distance which Dr. J. W. S. Cassels writes as $\|q\theta\|$. This specifies the homogeneous problem; the inhomogeneous problem concerns $\|q\theta - \alpha\|$, and each problem can be generalized to that of simultaneous approximation to a finite number of θ's. In Chapters 1 and 3 of this Cambridge Tract, the classical material is neatly and efficiently displayed. Chapter 2, a little more difficult, deals with the curious Markoff 'chain', which disposes of one exceptional θ after another, and the related results about quadratic forms; this includes a new and hitherto unpublished 'isolation' theorem due to C. A. Rogers. In Chapter 4 on the distribution of the fractional part of $q\theta$ in the interval (0,1) or of the simultaneous fractional parts for a finite number of θ's, the method of trigonometrical sums, due to Weyl and developed by Vinogradoff, is employed. The next chapter discusses a type of duality between problems concerning related (transposed) sets of linear forms, first examined by Mahler. Chapter 6 is particularly interesting, since it deals with Roth's theorem, that if ξ is any algebraic number, that is, a root of an equation:

$$a_0u^n + a_1u^{n-1} + \ldots + a_n = 0$$

where the a's are integers, then there are only a finite number of pairs of integers p,q such that:

$$|\xi - p/q| < 1/q^k$$

if $k > 2$. Since there are infinitely many solutions if $k = 2$, Roth's result is an end to a story which began about fifty years ago with Thue's remarkable theorem, that the equation:

$$a_0x^n + a_1x^{n-1}y + \ldots + a_ny^n = c \quad (n \geqslant 3;\ c \text{ integral})$$

(where the form on the left is irreducible) cannot have an infinite number of integer solutions x,y. To obtain this, Thue used a weaker form of Roth's theorem, with $k = \frac{1}{2}n + 1$, a value improved by Siegel (1921) and Dyson (1947), until in 1955 Roth closed the gap completely with the best possible value of k; notably it is independent of n. The International Congress of Mathematicians, meeting at Edinburgh in August this year, recognized the brilliance of Roth's work by awarding him one of its two Fields Medals.

If $C > 0$, the inequality $\|q\theta\| < C/q$ has infinitely many solutions for almost all θ, that is, save for θ's forming a set of zero Lebesgue measure. This is the basis of Chapter 7, on metrical theory, developed in a series of papers by Dr. Cassels during 1950–51. The final, rather highly technical, chapter discusses the Pisot–Vijiyaraghavan numbers.

Dr. Cassels has selected his material carefully and expounds it with crisp clarity. The volume is a genuine introduction, for the reader requires no special knowledge of number theory; even in the final two chapters, only a very rudimentary acquaintance with Lebesgue measure and with algebraic numbers is supposed. Yet the author manages to bring us into effective contact with several important lines of present-day research, and his book must rank high among the famous Cambridge Tracts. T. A. A. Broadbent

Conformal Transformations in Electrical Engineering

By Dr. W. J. Gibbs. Pp. viii+219. (London: Chapman and Hall, Ltd., 1958.) 45*s*. net.

THIS book is one of the series of advanced engineering text-books written by members of the technical staff of the British Thomson-Houston Company. It develops the mathematics of the electromagnetic field, the theory of complex numbers, conjugate functions and conformal transformations. Numerous practical examples are worked out in numerical detail, including configurations with n right angles where $n = 0,1,2, \ldots$, and a chapter is devoted to each of the first three values of n. The theory of elliptic functions and integrals is presented in several chapters, and in the last chapter examples of problems needing this theory are worked out. One of these is that of a succession of equal slot openings opposite a solid face (the theory here uses an elliptic integral of the third kind). Clarity abounds in this book. The printing is clear, the numerous diagrams are easy to understand and the exposition is not too concentrated nor diffuse. In fact, the classical subject-matter is treated in classical style. This even extends, unfortunately, to the references. Very few engineers will bother to consult the original papers (1867 and 1869) of Schwartz and of Christoffel, let alone read the German text. There is not a single reference to a paper after 1928, and the reader who wants access to more recent work will have to spend quite a time wading through the volumes of *Electrical Engineering Abstracts*.

Electrical engineers, especially those concerned with design, will be aware of the present-day tendency to the automatic use of an electronic computer for design, even in cases where a mathematical solution is possible. The superiority of the latter, especially for studies relating to the effect of parameter variation, is undisputed. Thus there is a real need to make available, in easily accessible form, a statement of how far one can expect to go in providing a mathematical rather than a purely numerical solution. The present book does this admirably so far as conformal transformations are concerned.

L. S. GODDARD

The Interference Microscope in Biological Research

By Dr. Arthur J. Hale. Pp. xi+114. (Edinburgh and London: E. and S. Livingstone, Ltd., 1958.) 20*s*. net.

THE interference microscope was developed to overcome certain deficiencies in the phase-contrast microscope. In my opinion it will never replace the latter for routine observational work, but its great advantage is that it can be used for measuring optical-path differences. From the biological point of view the fact that the optical-path difference is proportional to the dry mass per unit area of tissue opens up new fields of research concerned with 'weighing' living cells and tissue sections. Dr. Hale gives a very useful general account of the theory and practice of interference microscopy for the non-specialist reader. He begins with an account of light waves and their interference and ends with an appendix on wave-motion and polarization of light. The rest of the book deals with the various types of interference microscope, interpretation of images, measurement of optical-path differences, cytochemical calculations and sources of error. A possible criticism is that too much space is devoted to systems of only theoretical interest. Multiple-beam methods, for example, as Tolansky has stressed, are of very limited value in biology. The description of the Smith-Baker microscope, on the other hand, is rather incomplete, and the diagrams do not refer to the commercial instrument. No mention is made of the need to use a half-wave plate to interchange the ordinary and extraordinary rays and the explanation of the action of the Sénarmont compensator may puzzle some biologists. There is a useful summary of methods for deriving various cytochemical quantities; but no detailed examples of biological applications are given. Possibly more stress could have been placed upon the fact that most measurements with the interference microscope only provide the dry mass per unit area and not the total dry mass of a heterogeneous cell. The measurement of the latter quantity may require elaborate apparatus and may be extremely tedious. Until this limitation is overcome, the full potentialities of interference microscopy will not be realized.

R. BARER

Gas Chromatography

A Symposium held under the auspices of the Analysis Instrumentation Division of the Instrument Society of America, August, 1957. Edited by Vincent J. Coates, Henry J. Noebels, and Irving S. Fagerson. Pp. xii+323. (New York: Academic Press, Inc.; London: Academic Books, Ltd., 1958.) 10 dollars.

HERE are collected together twenty-seven papers on various aspects of gas chromatography which were presented at the symposium held by the Instrument Society of America in 1957, together with reports of the discussion which followed each paper.

The different topics covered include theoretical studies of gas chromatography, new experimental techniques, a variety of analytical applications, and the design and development of automatic process analysers. Some of the contributions are of outstanding importance in their field, and stimulated spirited discussion outside the formal sessions of the symposium; among these are the paper by M. J. E. Golay on the theory and practice of gas-liquid partition chromatography with coated capillaries; a paper by C. Phillips which describes the use of metal salts as stationary phases to obtain greatly enhanced separation of substances capable of forming complexes with those metals; and papers by B. O. Ayers, and by C. C. Helms and H. N. Claudy, outlining some of the problems encountered in the design and operation of automatic continuous process analysers. The construction of a laboratory gas chromatography unit capable of operation at 500° C. and above is described by H. R. Felton; this is noteworthy for its simplicity and extremely low cost in comparison with the majority of commercial instruments. The factors affecting the design and operation of thermistor-type katharometers are discussed in considerable detail by C. B. Cowan and P. H. Stirling, and a critical study of the copper-oxide combustion method of detection is contributed by S. D. Norem. This book is similar in general outline to the volume edited by D. H. Desty and C. L. A. Harbourn containing the proceedings of the Institute of Petroleum 1956 symposium, but its value is enhanced considerably by the inclusion of an excellent bibliography in addition to subject and author indexes; it can be recommended as a worthy addition to the literature on this subject.

N. H. RAY

THE ROYAL SOCIETY

ANNIVERSARY ADDRESS*

By Sir CYRIL HINSHELWOOD, P.R.S.

AWARD OF MEDALS, 1958

Copley Medal : Prof. J. E. Littlewood, F.R.S.

At the present time J. E. Littlewood is, by general agreement among mathematicians, by far the most eminent pure mathematician in Britain. His papers contain deep and difficult solutions of important problems, and have opened new fields for investigation. The papers on the minimum modulus of integral functions of finite order (1908) led the way to further developments, including a major problem only recently solved. The Tauberian theorem for power series (1915) was an important step forward from Tauber's original theorem and even from Hardy's Tauberian theorem for Cesàro summation, and might be regarded as the true beginning of what is now recognized as an independent subject—Tauberian theorems. Among Littlewood's results on the theory of functions he showed (1924) that the coefficients a_n of schlicht functions regular in the unit circle satisfy the inequality $| a_n | \leqslant en | a_1 |$ for all n; this constituted an important advance, and since then the problem of whether the constant e can be replaced by 1 has become one of the famous unsolved problems of pure mathematics. His proof (1914) that a long-standing conjecture about the number of primes less than a prescribed number is false is one of the surprises of modern mathematics, for the correctness of the conjecture is supported by all available empirical evidence, including numbers up to a thousand million. Mention must also be made of his extension of Fatou's theorem to subharmonic functions, and his excursion into the applied mathematics of anti-aircraft fire in the First World War.

Besides all this work which he did alone, Littlewood was an important member of the partnership so famous throughout the world that it has created a name, Hardy–Littlewood analysis, for a certain type of mathematics cutting across the natural boundaries of subjects just as its technique cut through difficulties. In the best kind of mathematical collaboration it is impossible for the authors to say to which of them any particular piece of work can be attributed, but Hardy's immense admiration for Littlewood, expressed in his "Apology" and verbally on many occasions, suggested that all the most difficult parts were done by Littlewood. Although Hardy was too modest, a certain kind of unexpectedness and difficulty is characteristic of much that Littlewood published independently.

He also collaborated with R. E. A. Paley in a very important series of papers on Fourier series, with A. C. Offord in a long paper (1948) on the distribution of zeros and α values of a random integral function, and with M. L. Cartwright on non-linear differential equations connected with radio. His work with Paley provided the starting-point for extensive investigations by others. His work on non-linear differential equations, begun in 1945, is still continuing and has covered a wide field, including some fixed-point theorems in plane topology suggested by the results on differential equations.

He has inspired many generations of pupils, and his lectures and book on the "Theory of Functions" have formed the starting-point for some of the most outstanding work by young English mathematicians.

Rumford Medal : Sir Thomas Merton, K.B.E., F.R.S.

Sir Thomas Merton has devoted himself to research in spectroscopy for close on fifty years. His early papers dealt with absorption spectra, but he soon turned to the emission spectra of gases and the causes of the variations in the spectra produced under different conditions. These were of particular interest in relation to the spectra of celestial bodies. In a paper in 1916 with the late J. W. Nicholson a most ingenious method of measuring the distribution of intensity in broadened spectrum lines revealed marked discontinuities in the intensity curves, pointing to the existence of several component lines. The application of the same method to the investigation of hydrogen and helium lines threw much fresh light on the transference of energy from one series to another under different conditions, and the distribution which is characteristic of some stellar radiators was reproduced in the laboratory for the first time.

Merton's Bakerian Lecture in 1922 on the spectrum of hydrogen cleared up a number of discrepancies in the secondary spectrum of hydrogen, which was shown to be due to the hydrogen molecule. It also emphasized the profound influence which traces of impurities can have on gas spectra. This was the subject of a number of subsequent papers dealing mainly with the influence of the rare gases on the spectra of other elements. All his work has been distinguished by the elegance and ingenuity of his experimental methods.

The rarity and expense of good diffraction gratings led Merton to devise in 1935 a method of copying them without loss of optical quality by applying a thin layer of a cellulose ester solution to an original plane grating. This pellicle he detached after evaporation of the solvent and applied its grooved surface to a moist gelatine film on a glass plate. After evaporation of the water the gelatine was found to bear a faithful record of the original rulings.

In 1948 Merton made an important basic advance in the science of ruling diffraction gratings. Since 1880 these had been ruled groove by groove by the method laid down by Rowlands. In place of this Merton ruled a very fine helix continuously on a steel cylinder which he then opened out upon a plane gelatine-coated surface by his copying method. No lathe could, however, rule a helix free from periodic errors of pitch, and these Merton eliminated by means of a very simple and ingenious device. It consisted of a 'chasing lathe' by which a secondary helix was cut on the same cylinder with a tool guided by a 'nut' lined with strips of cork pressed upon the primary lathe-cut helix. This device eliminated entirely the periodic errors, as they were averaged by the elasticity of the cork.

Merton then handed over these processes to the National Physical Laboratory for further development, and they have formed the basis of a considerable research programme. The 'blazed' gratings made by the Merton–N.P.L. method are already of great value in making available cheap infra-red spectrometers of high resolving power which are finding many applications in research and industry. The ruling of long gratings by this method has made possible their use as scales for engineering measurement and machine tool control.

---

* Delivered at the Royal Society on December 1.

Royal Medal (*A*) : Prof. H. S. W. Massey, F.R.S.

Prof. H. S. W. Massey is distinguished alike in the fields of experimental and theoretical research. His early experimental work was concerned with elastic and inelastic collisions between electrons and atoms. In collaboration with Bullard he carried out a series of experiments in which diffraction effects were demonstrated and studied in detail. With Mohr, and others, he carried through a large number of detailed calculations, and in particular he exploited the variational method with great thoroughness. His review in "Reports of Progress in Physics" (1942) did much to give a pattern to the experimental results by emphasizing the significance of the near-adiabatic conditions.

During the same period he contributed to the early theoretical treatment of neutron interactions, and somewhat later was responsible for a large volume of work on the binding energies of the simplest nuclei.

Massey has paid particular attention to negative ions. His writings on this subject systematized our knowledge and stimulated much research. He discussed for the first time why only some atoms can accommodate additional electrons to form negative ions, listing the various mechanisms by which these ions may be formed and destroyed. With Mott he wrote "Theory of Atomic Collisions", and with Burhop "Electronic and Ionic Impact Phenomena". These have come to be accepted as the standard accounts of their respective subjects.

Massey was the first to apply the theories of electron attachment and recombination to problems of the ionosphere, and he led the way in reviewing the results of experiments in this field and in trying to explain them. The difficulties in the way of any entirely satisfactory explanation led him to investigate and discuss a wide range of atomic and molecular processes which might be operative in the upper atmosphere.

It is not surprising that with the advent of the rocket as a means of upper atmospheric exploration, Massey should have made himself the pioneer British worker in this new field. Besides developing equipment for this work, he is heavily engaged in assembling more powerful apparatus for the laboratory investigation of collision process. His personal contributions to our knowledge of ionospheric physics are already considerable : the preparatory work going forward in his department makes it more than likely that the future contributions of the research team which he directs will be of equal importance.

Royal Medal (*B*) : Prof. A. L. Hodgkin, F.R.S.

Prof. A. L. Hodgkin has taken a leading part in nearly all the important advances in our understanding of the excitable membranes of nerve and muscle in the past twenty years.

His first experiments clearly demonstrated that local electrical currents, set up in the cable-like structure of the nerve fibre by the approaching impulse, were the stimulus which excited the next section of nerve. Hodgkin's experiments provided the first experimental proof that the local currents were of sufficient magnitude. Further direct evidence for this mechanism was his demonstration that the conduction velocity of the nerve impulse could be reduced by increasing the electrical resistance, outside the nerve, through which the local currents flow.

Hodgkin was a pioneer in measuring the electrical constants of nerves by square-pulse analysis ; he and Cole measured the core and sheath resistances of the squid giant nerve fibre ; later, with Rushton, he extended the method to measure the capacitance of the nerve membrane.

He was the first to observe and record the 'sub-threshold' responses of nerves and muscles when stimulated with currents too weak to initiate a propagated impulse.

Hodgkin was among the first to record the electrical activity of nerve and muscle with electrodes *inside* the single cell, a powerful and, eventually, much-used technique. He and Huxley found by this means that the resting potential across the membrane was reversed during the nerve impulse. Hodgkin and Katz then demonstrated that the reversal of potential varied with the external sodium concentration in a way which showed that the inward current was carried by sodium ions. These observations were followed by the discovery that the action potential was generated by the influx of sodium ions in muscle as well as nerve.

Hodgkin, Huxley and Katz studied the relationship between current and voltage in the nerve membrane. The currents were shown to be due to alterations in the permeability of the membrane to sodium and potassium ions, which were caused by changes of potential and accounted quantitatively for the propagation of the nerve impulse.

Through Hodgkin's researches we know that the rising phase of the nerve impulse (−70 to +40 mV.) is due to the influx of sodium ions, 3 $\mu\mu$moles/cm.^{2} nerve membrane/impulse at 15° C., sodium ions being pumped out of the resting nerve ; that the recovery phase (+40 to −70 mV.) is due to the efflux of potassium ions ; and that there is a compensating influx of potassium ions during the slower, metabolic, phase of recovery. Hodgkin and Keynes measured the sodium and potassium fluxes in both directions across the nerve membrane and showed that both were active processes.

All Hodgkin's work is elegant, conclusive and clear. He has applied new physical methods to biological problems and made quantitative measurements at every stage. It is largely owing to his work and influence that coherent and well-supported evidence now exists for the mechanism of nervous conduction.

Davy Medal : Prof. R. G. W. Norrish, F.R.S.

Prof. R. G. W. Norrish is distinguished for his many notable contributions to physical chemistry, particularly in the fields of the elucidation of photochemical change, the combustion of hydrocarbons and the development of experimental methods for the study of rapid reactions.

His early investigations of the catalysis of the intrinsically important reactions of the combination of hydrogen and chlorine and hydrogen and oxygen considerably clarified many features of these reactions. The general acceptance of the chain nature of these reactions, and the wider recognition of the occurrence of chain reactions led him to explore the mechanism of the photochemical dissociation of complex organic molecules, particularly the aliphatic ketones, and also to embark upon a considerable series of studies of the thermal and photochemical oxidation of hydrocarbons and related substances. These researches were of outstanding value in the understanding and interpretation of chain reactions.

Norrish then took up the study of the complex processes of addition polymerization and in this field he has made significant contributions. He and his co-workers were among the first to recognize the now well-known 'gel effect', and to elucidate the kinetics of copolymerization and the features of heterogeneous polymerizations. The ultimate development of Norrish's interest in the study of atom and radical reactions was the development and utilization of a high-intensity flash discharge lamp for the study of fast reactions. This method of 'flash photolysis' has become one of the most important techniques for this kind of work, and among other applications the method has been used successfully in the measurement of the spectra of new radicals, the study of rate of atom reactions and the investigation of explosive phenomena.

Darwin Medal : Sir Gavin de Beer, F.R.S.

Sir Gavin de Beer has made many contributions to the study and understanding of evolution. He early perceived that the mechanisms of individual development, at all stages from egg to adult, have an important bearing on evolutionary theory and that they must be taken into account equally with the facts of palæontology and comparative anatomy in framing a picture of the actual course of evolution.

Haeckel's famous theory of recapitulation asserted that the individual in its development ran through the successive adult forms of its ancestors, and that accordingly phylogeny in some way determined ontogeny. De Beer, in his "Embryology and Evolution" and successive editions of his later book "Embryos and Ancestors", has done more than any other biologist to show that Haeckel was wrong—that recapitulation, if present, is always the recapitulation of ancestral developmental stages, not of ancestral adult forms ; and that it is changes in ontogeny and its mechanisms which actually influence the course of phylogeny, and not vice versa.

In particular, he generalized the important concept of paedomorphosis, by showing how various types of retardation of various ontogenetic processes would result in the prolongation of juvenile characters into the adult phase. He thus demonstrated the importance of this anti-recapitulatory process for many notable evolutionary events, including the origin of insects from myriapods, and our own origin from an anthropoid stock.

For these studies he drew largely on his wide knowledge of experimental embryology, summarized in his joint volume with J. S. Huxley in 1934, as well as on his own monumental study of "The Development of the Vertebrate Skull" (1937). From this latter work he drew the conclusion that the earliest vertebrates had bony skeletons, and that the formation of cartilage was originally limited to the early stages of ontogeny. The cartilaginous skull of elasmobranchs is thus not ancestral, but neotenous, resulting from the prolongation of an embryonic condition into adult life and not from the recapitulation of an earlier adult condition.

In 1947, by his ingenious work confirming the origin of the urodele visceral skeleton from cells of the neural crest, he helped in finally burying the germ-layer theory in its original dogmatic form.

With equally ingenious methods, as director of the British Museum (Natural History), he was able to discover important new facts about the brain and breastbone of that precious fossil, *Archaeopteryx*, and to demonstrate that it was still incapable of manœuvrable flight.

Sylvester Medal : Prof. M. H. A. Newman, F.R.S.

Prof. M. H. A. Newman's work can be described under three headings :

(1) *Fixed point theory and continuous groups.* In 1900 Hilbert proposed the problem of showing that the analytic character of a continuous group follows from its continuity alone. This was proved by Brouwer for two-dimensional groups in 1910. In 1931 Newman proved it for commutative groups of arbitrary dimension. In this proof the basic lemma is that such a continuous group does not have arbitrarily small sub-groups. The proof of the lemma depends on an investigation of the fixed points of periodic transformations.

The later work of Newman on Hilbert's problem was not published and was rediscovered independently by Montgomery, Zippen and Gleason, who extended the basic lemma to non-commutative groups and gave a final solution to Hilbert's problem in 1952.

His most striking recent result was an elementary proof of the formidable fixed-point theorem of Cartwright and Littlewood.

(2) *Pure combinatorial topology.* This is the very difficult part of topology in which continuous mappings of manifolds are replaced by combinatory transformations of finite cell complexes. In 1926, Newman gave new life to this subject by completely refounding pure combinatorial topology using simplicial complexes and a new system of elementary combinatory moves. He showed the effectiveness of the new methods in a series of ten papers in which several famous problems were solved. All later work on the subject is based on Newman's results.

He ceased systematic publication on this subject in 1932, though he is known to have continued working on the conjecture of Poincaré and Steinitz that every manifold can be represented as a simplicial complex and that homœomorphic manifolds are simplicially equivalent. Interest in pure combinatorial topology has revived in the present decade since Moise, using methods similar to those of Newman, has proved the Poincaré and Steinitz conjectures for three-dimensional manifolds.

(3) *Applications of combinatorial methods.* After 1932, although very little of Newman's work on topology was published, he continued to publish a number of papers on logic, lattices and other applications of combinatory methods. He also published an important introductory text-book, "The Elements of the Topology of Plane-Sets of Points".

In 1941 Newman published a remarkable axiom system for Boolean algebra, and in 1943, in a paper on stratified systems of logic, he developed a general method covering the different type theories proposed by various mathematical logicians.

Hughes Medal : Prof. E. N. da C. Andrade, F.R.S.

Prof. E. N. da C. Andrade's experimental investigations have covered a wide field of physics. He elucidated the mechanism of a series of classical phenomena in sound. He demonstrated the method by which sand particles on a vibrating plate are brought to adopt the observed positions, the causes of the peculiar arrangements of the particles in the Kundt's tube, and the reasons for the characteristic behaviour of the sensitive flame. In the Kundt's tube he obtained experimentally the slow circulation predicted by Rayleigh, but not previously observed. Further, he has made considerable contributions to the domain of viscosity of liquids, including liquid metals; and to metal physics, including the properties of single crystals.

Andrade has derived a formula for the variation of viscosity with temperature. He has also derived a formula which gives the viscosity of a liquid at the melting point as a simple function of the atomic weight, density and temperature, free of any arbitrary constant. This formula has been used with success to predict the viscosity of liquid helium. His formula for the variation of viscosity with pressure yields exact agreement with the observed value of the only available monatomic liquid, mercury, at a pressure of 12,000 atmospheres. Andrade has also established the (very small) effect of an electric field on the viscosity of a liquid, an effect which had been vainly sought for more than sixty years.

In metal physics Andrade has done much original and ingenious work. In the investigation of creep he has shown the importance of maintaining constant stress instead of constant load, as was done by earlier workers in this field, and has given various mechanical methods for maintaining constant stress. He has established the laws of creep, dividing the process into two distinct parts, a temporary and a permanent creep, the first due to slip on crystal planes within the crystals, the second or permanent flow, which is important at high temperatures, being due to relative movements of the grains as a whole. The relative importance of the two forms of creep has been shown to depend on the temperature relative to the melting point. His early work on creep is considered fundamental in recent books on the subject.

Andrade has also developed methods of making single crystals of metal, in the form of wires or rods, and has investigated the nature of the glide planes. It was he who first established the 'easy glide' which can take place with cubic crystals, while a recent paper with Aboav extends the earlier work of Andrade and Henderson in which the 'easy glide' was established. Andrade also demonstrated the effect of surface conditions on the properties of metals.

SOME MODERN SCIENTIFIC THEMES

If, as some of us believe, natural science is to-day the foremost of humane studies, we cannot be indifferent to its great central themes: the nature of the cosmos, the origin in time of its present ordering, the law (cyclic or otherwise) of its evolution, the stuff of which it is made; waves, particles, and their ways, their mutual relations and their metamorphoses; the genesis of the chemical elements; the operation of the laws of chemistry and physics to determine the spectacle of material vicissitude; the origin of life, the evolution of its multitudinous forms, the manifestation of its properties and the correlation of these with the physicochemical principles which somehow underlie them.

In the scientific literature of a limited period the main lines of progress are not easy to make out. Occasional great discoveries burst on us like revelations, but mostly only trends are visible. The different contributions, moreover, are often expressed in quite different idioms, some indeed being scarcely intelligible except in the language of specialized symbolisms. Yet it behoves us to try to see where science stands and where it is going, and from this point of view I shall refer briefly to some of the trends and characteristics of the work of the very recent past.

Cosmology is in a state of flux in almost every possible sense. The present order of things, it now appears, has lasted something like 10^{10} years. Evidence from the 21-cm. radiation of hydrogen revealed the spiral structure of the galactic system, and now our estimate of the whole scale of the stellar universe has suddenly been enlarged by the observations of Sandage. The 200-in. telescope has during the past year revealed that some distant objects thought on the evidence of the 100-in. instrument to be stars are in fact associations, and in consequence the accepted distance scale must be greatly increased, according to one line of argument by a factor of several times.

The radio telescope is contributing much to work on the structure of the universe, and the past year has seen major advances in technique. The possibility that some of the radio sources may be colliding galaxies beyond the range of optical telescopes shows the significance of the new methods. It may also be hoped that observations, from artificial Earth satellites, of radiation in wave-lengths absorbed by the Earth's atmosphere, may lead to further discoveries about the happenings in the depths of space. This is perhaps one of the best of reasons for launching these bodies.

Our general conceptions have long been largely dominated by the apparent continuous expansion inferred from the infra-red shift of spectral frequencies. This recession of nebulæ was recently interpreted by Holmberg in terms of a special geometry where velocity and position are complementary quantities and where the equations provide that what is interpreted locally by one observer as displacement is interpreted by a distant observer as velocity.

How much value we attach to translations into geometrical formalism really depends upon a philosophical attitude. The earliest great synthesis of Nature, the theory of gravitation, later received a famous geometrical interpretation in the general theory of relativity. But other explanations based on the particle-exchange conception familiar in chemistry and nuclear physics have been sought, and have very recently been revived, with the neutrino in the role of the binding particle. The outcome is uncertain but it would be æsthetically satisfying if, as it were, the infinitely great and the infinitely small were thus brought into relation.

According to some theories, there is an endless renewal of cosmic cycles, determined by extremely rare collisions between stars: new galaxies are formed from the debris of old, new stars are born and the chemical elements are rebuilt from the undifferentiated nuclear matter of hyperdense stars. However this may be, cosmology and nuclear physics here come into strikingly close relation. A reasonably plausible though complex set of hypotheses is emerging about the manner in which the chemical elements are formed by 'hydrogen burning', 'helium burning' and by neutron capture processes in the stars. The details depend largely upon the evidence of nuclear collision processes studied in the laboratory, and on calculations based on the results. In spite of all uncertainties and complications, a most impressive picture emerges of the origin and relative abundance of the elements.

In contrast with the abstract formalism of parts of the theory, it is interesting to note in nuclear chemistry and physics generally how much is still being done in a relatively simple manner. Nuclear syntheses, at temperatures of the order 10^8 deg. K., are treated in a way resembling on a vastly magnified energy-scale the familiar calculations of chemistry. The synthesis of carbon-12 from three α-particles, to take one example, is envisaged as occurring in the steps:

$$2\alpha + 94\,\text{keV.} = {}^{8}\text{Be}$$
$${}^{8}\text{Be} + \alpha + 278\,\text{keV.} = {}^{12}\text{C}^{*}$$
$${}^{12}\text{C}^{*} = {}^{12}\text{C} + 2\gamma + 7{\cdot}65\,\text{MeV.}$$

and the rate of the reaction is estimated by an integration of the Maxwell energy distribution of α-particles over each of the relevant resonances.

Theories of this kind, like the planned synthesis of isotopes, have something of the character of structural chemistry in its heyday; and indeed a whole chapter of nuclear chemistry dealing with synthesis, fission and so-called spallation reactions operates in terms of quite elementary ideas, odd or even numbers of neutrons and protons determining stability and frequency of occurrence of nuclei, and the likelihood of their fission after neutron capture. It is interesting to note in passing that recent estimates, based upon reasonable extrapolations, predict the possibility of nuclear masses a good deal higher than was at one time envisaged. The original synthesis of element 102 has been called in question, but a new production by a different method is simultaneously claimed. (Even this situation has echoes of the classic days of synthetic organic chemistry.)

Reduced to its simplest terms, the project of harnessing the energy from nuclear fusion in the reactions D + D or of D + T is the old problem in reaction kinetics of raising gases to an ignition temperature, where the heat evolved from reaction exceeds that needed to provide the activation energy and balance the losses. Temperatures of nuclear transformations are about six orders of magnitude greater than those of ordinary chemistry. Thus what is now being brought near to realization is the application of advances in electrical engineering to render possible in the laboratory what a few years ago appeared possible only in the stars.

The translation of traditional physical chemistry far up the energy-scale raises an interesting speculation. In certain chemical reactions, branching chains lead to the existence of critical pressures where abrupt transitions from slow reaction to explosion occur, and the same pattern exists in the phenomena of critical size in nuclear fission. In chemical systems special conditions are known where the branching and quenching of chains give rise to periodic flames. It is an interesting question whether perhaps eventually the chain reactions of stellar alchemy may even explain in an analogous way the mystery of the Cepheid variables.

One of the profoundest problems facing science to-day remains that of the so-called elementary particles themselves. The subject is no easy one, and throughout its description the abstractly formal and the naïvely pictorial interplay with curious contrasts. The entities in question are, in fact, neither elementary nor in the usual sense particles, yet in some way they, or some of them, are the stuff of which everything is made.

Even in the bizarre and scarcely credible world of mesons, neutrons, hyperons, 'strange' particles and the like, there occur phenomena still oddly reminiscent of the simpler kinds of chemistry. 'Positronium' is now known in its *ortho* and *para* forms; mesonic atoms have been detected. Mesons can be made to function as catalysts for nuclear reactions, as, for example, in the bubble chambers where there occurs the reaction (Jackson 1957):

$$\mu^{-} + p + d \rightarrow {}^{3}\text{He} + \mu^{-} + 5{\cdot}5\,\text{MeV.}$$

with a mesonic atom as a probable intermediate. Another example of the relatively simple analogy is to be found in the so-called shell model of the nucleus, which has been yielding useful results by methods not unfamiliar to the spectroscopy of a generation ago. Reactions provoked by the antineutrino flux from the β^{-}-active fission products of a uranium-235 pile provoke reactions such as $p(\bar{\nu}, \beta+)n$, in striking vindication of what once used to seem a mathematical fiction.

Yet the homely analogies fail when confronted with the attempt to interpret the nuclear particles themselves, and the physics of their generation, mutual interaction and decay. Some completely new principle, it seems, is needed before this subject assumes the form of a coherent and intelligible body of doctrine.

More and more remarkable facts are being revealed, largely by the technique of scattering experiments, carried out with the aid of the great accelerating machines. The principle is a simple one, beams of particles of the appropriate character being passed through a material presenting an array of obstacles, such as electrons or nuclei. What may crudely be termed collisions occur, and the incident beam is replaced by an attenuated transmitted one together with a scattered beam, the intensity, character and angular distribution of which is determined. It is in this, as well as in the arrangements for the generation of the beam, that varied and ingenious, elaborate and costly methods are called for. The theoretical treatment of these problems is based upon the equations of quantum mechanics and necessarily assumes an abstract and formal character. The density of particles in the incident beam is represented as a function of the spatial co-ordinates by one wave, that of the scattered beam by another. The relation between the two involves, apart from certain general requirements of continuity, the function representing the potential energy of the interaction between the two kinds of entity concerned in the collision. This function for various kinds of interaction is one of the main objects of research, and its determination depends upon complicated and often subtle characteristics of the intensity distribution. Enormous effort is being expended on this problem, but a satisfying theory of nuclear forces is still lacking.

In the curious picture of tidiness and complexity which nuclear particles present, the element of symmetry, so strikingly extended by the discovery of the antiproton and the antineutrino, has been strengthened by the appearance of the antineutron, which is produced in the process:

$$\text{antiproton} + \text{proton} \rightarrow \text{neutron} + \text{antineutron}$$

The antineutron, like the neutron, has no charge, but differs from it in that its magnetic moment is parallel instead of antiparallel with its spin angular momentum.

Questions of spin and symmetry, though belonging to the abstract rather than the naïve modes of interpretation, can be more vividly apprehended than most of the former group and are clearly fundamental to the nature of things. The problem of the conservation of parity has naturally roused much interest, and this subject formed the theme for a Royal Society discussion meeting early in the current year. Despite the rather deep significance of the parity question, it seems to be agreed that the practical consequences in physics of the non-conservation are much less drastic than other failures of conservation might be.

Thus by minute but immensely significant brush strokes the grandiose picture can be seen slowly emerging. The abstruse bombardment and scattering experiments of physics probe at the secret of the strange and often transient microcosmic entities while the 200-in. telescope and the radio telescope, presently perhaps to be reinforced by instruments carried by satellites, penetrate the depths of space to find the secrets of the macrocosmic entities. Within the greater entities, the lesser, under the impulse of almost Pythagorean laws, yield the chemical elements, and the greater, themselves transient on their own vast time-scale, evolve planets, where organic substances can be synthesized and life appears.

In the second half of last year the Moscow conference on the origin of life brought to focus a further series of interrelated problems. Cosmology and geology determine the initial possibilities, which depend upon the original terrestrial atmosphere. This probably was a reducing one containing methane, ammonia and hydrogen, from which amino-acids, and by stages a complex store of organic compounds, could be accumulated. According to one view, there must have arisen at some stage self-reproducing mechanisms within semi-liquid colloidal systems, a process not necessarily dependent on enormous improbabilities, since it could occur in stages, prefabricated units of one order of complexity uniting to give constellations of a higher order.

Once living material has been formed, natural selection operates on it. In the centenary year of the historic paper of Darwin and Wallace, this principle is not likely to be forgotten. It has long dominated biology, and in one form or another is incontestable. Heritable mutations or new combinations leading to a finite advantage will of course prevail. Too often, however, people have been content to leave it all at that and to treat the real problem as though it did not exist. What is the nature of a mutation, and, a much profounder question, by what means does it express itself in the organism ? We cannot be content with vague assertions that the possibilities of life are infinite. Selection presupposes something worth selecting; in a war-time market the shopping capacities of the best housewife are of little avail.

Recently the custom has grown of speaking of codes or programmes contained in the structure of the deoxyribose nucleic acid of the cell. Vast macromolecules composed of alternating sequences of varied units can, evidently, in their permutations and combinations, provide a code for anything. After all, the twenty-six letters of the alphabet can express the whole of human knowledge. But at least as important, and much harder to visualize is the working of a machine to translate the code. The interrelation deoxyribonucleic acid – ribonucleic acid – protein governs the growth of the cell, with its enzyme complement and characteristic reaction pattern. The relation of the cell to the tissue, and of the tissue to the organized plant or animal, is not, after all, made much easier to understand simply by the principle that efficient self-replicating systems once established will displace less efficient ones.

The sequence of events by which the genetic code is operated is highly complex, and at certain stages of it there might be crucial points such that a small change in the code directs development along widely different paths. A phenomenon of this kind would perhaps satisfy the need of those who have felt some doubt, not of the truth and efficiency of natural selection, but of its ability to say everything that is worth saying about the origin of species. No metaphysical principles, of the kind rightly deplored in science, are involved in asking whether a certain discreteness in species may not be inherent in a corresponding discreteness in the admissible solutions of the equations which relate the possible growth-forms of an organism to the basic genetic pattern. Discontinuities arise in analogous ways throughout chemistry and physics.

The working of the machine by which genetic information is translated into cells and into complex individuals and by which it determines species is thus really the central problem of biology. The problem is being studied at many levels, and in many ways ; by work on the basic chemical structures themselves, on changed amino-acid sequences in the proteins of mutants, on the persistence of biochemical functions in living material after disintegration of entire cell structures, on the separation and reconstitution of virus components, on interference with virus growth, on the unbalanced growth of cells exposed to abnormal conditions, on adaptive phenomena in intact cells, on the earliest stages of embryonic development, including the effects of chromosome defects and of nuclear transplantation.

Naturally enough, much interest centres in the nucleic acids themselves. There is no question of the importance of their pattern, though even here it would seem to be unfortunate if exclusive preoccupation with this one aspect condemned to neglect all the other aspects of cell organization and structure Indeed, in connexion with virus reproduction, Fraenkel-Conrat, Singer and Williams concluded tentatively that "the protein may after all have a minor influence in the replication process". It would indeed be surprising if anything short of the complete structure and the entire organization of a cell completely determined its reproduction.

In seeking to fit the individual pieces of the specialized literature into their places in a coherent pattern, a classification into those dealing primarily with form and those dealing primarily with function may be made as a matter of rough convenience.

Pure form is illustrated by the many chemical studies on the structure of nucleotides, nucleic acids polypeptides and protein which are made by physical and chemical methods, both analytically and synthetically. As recent examples out of many, I might quote on one hand the synthesis of peptides containing sequences found in the natural compound argenine vasopressin, and on the other a hypothetical establishment of the complete amino-acid sequence i glucagon (a material of pancreatic origin).

Function can be studied in many ways. One is the careful observation and interpretation of the behavi our of intact cells in growth and adaptation. Another is the detailed study of individual enzymes and their 'induction' (Monod, Pollock). Such work has been widely discussed in recent years. Lately, much attention has been given to methods which seek, as it were, to analyse the function of the cell into single elements. One is by the investigation of the biochemical potentialities of cell extracts, and cell fragments, mitochondria, protoplasts and so on, and of the related question of 'metabolic pools' in cells. Cells can be broken down by various methods, by the use of lysozyme, sonic vibrations, various grinding procedures and by centrifugation which separates particles of different sizes from cell walls and supernatant fluid. The enzymatic functions of different fractions can be tested, and the relative proportions of different constituents in the various fractions determined. The localization of functions in the various size-ranges appears to vary with the organism studied and with the technique of disintegration employed. Sometimes a given function is shown predominantly by one fraction, for example, the supernatant fluid left after centrifuging, sometimes by several fractions. These and other complex observations obviously bear upon the question of internal organization in an important way, though almost any conclusion of general interest rests upon some very specialized and detailed judgment about the significance of given elements in the technique.

One observation of great interest is that of Roberts and collaborators, who find that a clear preparation of certain cellular juices to which manganous ions are added may, after a period of delay, give rise to particles (to which the term 'protomorphs' is given). These possess variable synthetic ability and seem to represent an intermediate state between the organization of the cell and the disorganized condition of the juice. As another example may be quoted the observation (Utter, Keech and Nossal) that yeast cells contain sedimentable subcellular units which have enough organization to effect complete biochemical reactions.

These and many other observations show that the organization of the cell is departmentalized and perhaps in a hierarchical manner, protein and nucleic acid being in a structural relation within particles, and particles themselves forming structural arrays in the cell. There is, however, a limitation to this approach. If a factory capable of manufacturing entire motor-cars were bombed it might be capable soon afterwards of turning out engines but not chassis or vice versa, or the electrical supply might be intact and the water cut off, and so on. Much could be inferred from careful observation, but nothing would really replace a study of the working of the intact installation.

Intact cells studied under abnormal conditions have yielded very valuable observations, of which I can quote only a few. In the presence of certain drugs protein synthesis may be held up while ribonucleic acid synthesis continues. In one system it was found (Ben-Ishai) that if ribonucleic acid is formed without protein, and then protein synthesis is allowed to occur afterwards, the preformed ribonucleic acid does not participate in this synthesis, which is linked only with that of the deoxyribonucleic acid simultaneously made. Certain mutant bacteria studied by Cohen required thymine and will not multiply in its absence, being unable to synthesize the deoxyribonucleic acid necessary for cell division. They may, however, form protein and ribonucleic acid, and the resulting unbalanced growth may eventually prove lethal. If the mutant also requires a specific amino-acid, withholding this restrains the unbalanced growth and increases the ultimate survival. A strain requiring both thymine and phenylalanine was incubated first in phenylalanine without thymine and then vice versa : something occurred in the first stage which permitted in the second stage a doubling of the deoxyribonucleic acid without formation of ribonucleic acid—an elegant example of control. A somewhat similar control operates in the process whereby cells from which thymine is withheld can be brought into a state where addition of thymine will cause all to divide together, a 'synchronization' process, which had been earlier effected by manipulation of the growth-temperatures of cells.

Division is largely determined by deoxyribonucleic acid. Deoxyribonucleic acid is the most important seat of hereditary characters. What may well be an enlightening glimpse of the first stage in the translation of the code is provided by the work of Holt and his collaborators. By special staining devices they locate areas of specialized enzyme activity in the cell. In rat-liver cells, enzymes having normally a peripheral distribution gather together during the process of mitosis and cluster towards the nuclear region, themselves going through a characteristic series of movements before dispersing finally to the surface regions of the daughter cells. This intimate communion of enzyme material with the nucleus during the mitotic process is an impressive reminder that the cytoplasm should not be regarded as an inert passenger without significance in reproduction.

Proteins and nucleic acids, genes, chromosomes and nuclei, cells, and early embryos are thus yielding suggestive glimpses of the fundamental mechanisms of the biological machine. Further clarification calls perhaps for a little more boldness in the study and analysis of hypothetical models, though in parts of the subject some of these are indeed being tested. Models in the more fundamental parts of physics are out of fashion, perhaps gone for ever, but in biology they remain a powerful aid ; not only in the chemistry and physics of cells, but also throughout physiology, up to the working of the nervous system and the operation of the brain itself.

Of brain function there is a crude and distant, but fascinating, reflexion in the operation of electronic calculators. In one of the latest of these, constructed by Uttley, statistical information about the pattern of input activity is accumulated, a leakage device ensuring that recent events have a greater influence than earlier ones. The result is that the machine operates in a way which in everyday language can be likened to learning by experience. The comparison may not prove to be a valid one, but it is even more interesting and provocative than anything I have yet seen in discussions about the other end of the scale, where the nucleic acids first begin to direct the development of any living organism.

So from the abysses of space where the elements are evolving and worlds are forming to the human brain which thinks about it all the story is unfolding. No detail of it is won without expert labour much of which is beyond the power of the layman to judge. But let us not forget the ends to which it is directed. It is all too easy to think of detailed and absorbing work as an end in itself ; but in so far as we may yield to the temptation, science will fail to occupy that place in the scheme of things which is its rightful due.

MOTILITY OF THE SPERM FLAGELLUM

By Dr. DAVID W. BISHOP

Carnegie Institution of Washington, Baltimore

SIR JAMES GRAY has admirably analysed the nature of the complex pattern of flagellation in the spermatozoa of the sea-urchin and the bull[1,2]. In both species of sperm a co-ordinated activity involving two major components of motion has been indicated—a propagated uniplanar wave initiated at the proximal end of the flagellum, and a superimposed longitudinal rotation upon the axis of propulsion due to a third-dimensional thrust by distal elements of the tail. The roughly helical pathway which results, albeit a tight spiral, is thus inherent in flagellar activity. It is not to be attributed, for example, merely to an asymmetrical configuration of the sperm head, which might convert a simple two-dimensional beat into an apparently three-dimensional movement of the entire cell.

The relation of mechanics of rotation to propagation of the vibrational wave appears to be quite different in these two types of sperm. Longitudinal spinning in sea-urchin sperm occurs at the rate of about 3/sec., whereas the vibrational wave-frequency averages 33/sec.; the two are thus relatively independent. In bull sperm, on the other hand, the rate of rotation corresponds closely to the frequency of the bending waves, 8–9/sec., and the two therefore seem interrelated. It was suggested that the bull sperm undergoes rotation as a result of a slight twist in the tail where the bending wave passes over the distal region. An alternative explanation was that a torsional wave accompanies the bending wave in its propagation along the flagellum[2].

The ultimate elucidation of these and other details of sperm motility will, of course, have to await further morphological clarification of the ultrastructure of the cell, particularly that afforded by the electron microscope. An explanation of the mechanics of movement will also depend on the biochemical identification of the precise elements involved in the processes of contraction, compression, and co-ordination of the flagellum. However, certain current observations of sperm, admittedly subject to highly unorthodox procedures, have some bearing on this problem and constitute the substance of this article. The two modalities of movement, indicated by Gray, can be separated and, in a sense, analysed individually. Their 'uncoupling' permits a consideration of the mechanics of waves as opposed to the propagation and co-ordination of waves. At the risk of attempting to tie up too much in one bundle, a tentative and simplified hypothesis of sperm flagellation is suggested.

The motility of spermatozoa, freshly exploded from the spermatophores of the common squid, *Loligo pealii*, is characteristically a violent, lashing, three-dimensional phenomenon. When such preparations are allowed to age, changes in motility, as might be expected, are pronounced. Sperm activity is very much decreased, as is fertilizing capacity; in this sense the cells are pathological. Nevertheless, with this caveat well in mind, we have found their slow motion to be a useful subject for study since they are not so seriously impaired that they cannot clearly respond, by a prompt increase in motility, to the addition of adenosine triphosphate in sea water.

In such slowly moving spermatozoa two kinds of movement may be readily distinguished. The more vigorous activity consists of a two-dimensional bending wave, asymmetrical with respect to the longitudinal axis and limited to the proximal segment of the flagellum (Fig. 1). The duration of wave formation compared with that of wave dissipation is of the order of 3 or 4 to 1, with a perceptible pause between beats. Bending, presumably the contraction phase, thus occurs gradually; straightening, the corresponding relaxation phase, occurs abruptly. Such wave formation can occur rhythmically without propagation along the flagellum. This uniplanar vibration may or may not be accompanied by the rotational movements discussed below.

Of the cells which could be clearly observed to undergo this slow-paced steady rhythm, fully 80 per cent bent in the plane and in the direction of the mitochondrial spur, a prominent characteristic of the mid-piece of the squid sperm. Thus, a relation exists between the asymmetry of the cell and the orientation of the vibration. The structural correlation of the spur with the ultrastructure of the axial bundle, and the additional correlation of the fibrillar arrangement with respect to the direction of beat of the flagellum bear further investigation. A relation of fibrillar orientation to direction of beat has indeed been established for cilia[3], and suggested for sea-urchin sperm[4].

The second and less-vigorous type of motility seen in ageing squid sperm is a rotation on the longitudina axis at the rate of 3–4 revolutions per second. This movement is generated by the distal region of the tail and, as in the sea-urchin sperm, the rate is very much lower than is the frequency of distal flagellation Spinning may occur in straight, otherwise motionless sperm as well as in those cells which also display the vibrational wave. The direction of rotation, which can be observed by virtue of the projecting spur, is predominantly counter-clockwise, viewing the sperm head-on (Fig. 1).

Thus, in these retarded squid sperm, motility, while far from the co-ordinated rapid movement of normal cells, proves to be basically similar to that recorded for sea-urchin sperm[1]. An added feature concerns the close correlation of the plane of two-dimensiona vibration with the gross asymmetry of the mid-piece

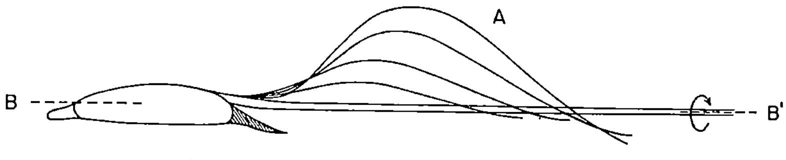

Fig. 1. Components of squid sperm motility. (1) Two-dimensional bending wave, *A*, initiated proximally, parallel to plane of mid-piece spur (cross-hatched). (2) Rotation upon longitudinal axis, *B–B'*, generated by distal region of flagellum

of the squid sperm. The significance of the difference in direction of rotation is not clear.

Certain aspects of sperm motility can be analysed in a totally different way—again of sperm exposed to highly unorthodox but controlled procedures. Sperm of several species of mammals (rabbit, rat, mouse, guinea pig, bull and man) have been prepared as glycerine-extracted cell models[5] comparable with the muscle-fibre systems introduced by Szent-Györgyi[6]. Such models have presumably lost all soluble inorganic and organic substances, their permeability has been destroyed and their ionic balance upset; the contractile and structural proteins, however, prove to be functionally intact. These models, parenthetically, are morphologically normal as seen in the phase microscope. Unlike muscle-fibre models which contract only once upon the addition of adenosine triphosphate, sperm models assume a persistent rhythmic activity which lasts many minutes or hours; in a very real sense, the contraction–relaxation cycle is self-perpetuating[7]. The flagellation is frequently as vigorous and may even exceed the frequency of beat of fresh sperm. Wave amplitude approximates that of normal vibration, 6–8μ. The entire tail can be involved or only short segments located proximally or distally along the flagellum. Bending waves develop from both sides of the longitudinal plane, implying the presence of contractile elements along both sides of the tail. Two limitations, however, distinguish the motility of sperm models induced by adenosine triphosphate from that of normal cells. The models show neither wave propagation along the flagellum nor rotation upon the longitudinal axis. Moreover, they fail to undergo any significant forward progression, despite the vigour of their movements.

The study of such extracted sperm models leads to the conclusion that, while inherently generated bending waves similar to those of normal contraction–relaxation cycles occur, both wave propagation and co-ordination are absent. Repeated efforts to restore these missing elements to the motile process by adequate adjustment of the ionic balance have been quite unsuccessful.

What emerges, then, from observations on such aberrant cells in relation to motility in normal spermatozoa ? Confirmatory evidence is provided for the existence of two discrete components of flagellation. Wave formation, as a mechanical and chemically generated process, is distinct from wave propagation and co-ordination leading to helical motion. The energy for vibration is distributed along the flagellum and distal oscillation does not require visible proximal wave bending. Bending couples may involve only segments of the flagellum; there is no evidence to indicate that a tensile element, extending throughout the tail, must contract in its entirety, whether this be visualized as a straight or a twisted fibril system[8]. Wave formation normally seems to be initiated at the basal corpuscle or mid-piece and to travel distally in a propagated manner.

Should rotational activity depend on a twist in the contractile or in the compressive elements of the tail, the twist must be sought in the distal region of the flagellum. If the distal helical flagellation depends on co-ordination from the proximal end, this conductile system may be lost altogether concomitantly with failure of wave propagation (for example, sperm models), or may persist despite the absence of a propagated vibrational wave (for example, squid sperm). In both types of sperm, however, the rate of terminal flagellation is high, the slow roll of the squid and sea-urchin sperm being a false index of the frequency of oscillation.

To what extent are these findings consistent with the ultrastructural picture of the sperm ? The more recent electron microscopic investigations of spermatozoa indicate that the fibrillar arrangement of the flagellum is more complex than that represented by the well-nigh universal, simple 9 + 2 or 2(9) + 2 system of longitudinal filaments[9–11]. Superimposed upon the basic radial symmetry is a bisymmetry provided by the two central filaments and the individual differentiation of the peripheral fibrils[12,13]. Such an arrangement, most prominent proximally, affords a physical basis for envisaging an oriented vibration in a single morphological plane, a wave characterized by a prevalent direction of effective beat and asymmetrical bending. The elegant electron micrographs of sea-urchin sperm tails prepared by Afzelius further suggest that cross-links ('side arms' and 'spokes') may connect adjacent peripheral fibrils and interconnect these with the central pair[4].

The contractile elements are generally regarded as located in the nine peripheral double fibrils of the flagellum. Evidence for this is largely circumstantial, but nevertheless considerable[4,9,14,15]. The function of the two central fibrils is somewhat in doubt, but they are to be regarded as relatively rigid supports and mainly responsible for the determination of the direction of vibration[4]. The structure and function of the cytoplasmic 'matrix' and of the prominent fibrous sheath, or 'cortical helix', of mammalian sperm are also poorly understood. Judging, however, from the gradual taper from proximal to distal end of the flagellum of many kinds of vertebrate sperm, from the relative nakedness of the terminal region of some flagella, and from the obvious differences in bending characteristics from fore to aft[1,2], the resistance to oscillation appears to decrease with passage of the propagation along the tail to the tip.

Any hypothesis of sperm motility at this time can be only tentative at best; nevertheless, sufficient information is available to project an intracellular system along the following lines. Flagellation is due to a series of rhythmic contraction–relaxation cycles performed by the activity of contractile proteins comparable to those of muscle. Locomotion results from a combination of two discrete components. (1) Two-dimensional waves initiated proximally in the region of the basal corpuscle are self-propagated distally. All or some of the nine peripheral fibrils respond, but the fibrils of maximum effective bending (for example, Nos. 5 and 6; cf. Bradfield[9]; Fawcett[3]) exert the most tension, or are stimulated most effectively, and establish the pattern of the bending wave. Each contraction wave is necessarily followed by a counterwave, out of phase, which passes down the other side of the axial bundle (for example, Nos. 1, 2 and 9). The interaction and the perpetuation of these successive contraction–relaxation cycles, as well as the events of the single contraction–relaxation cycle itself, are inherent in the biochemical properties of the contractile elements and are at present only poorly understood. (2) Three-dimensional rotational waves are generated by the distal region of the tail and are due to the other 'minor' peripheral fibrils exerting their influence relative to that of the 'major' fibrils responsible for the two-dimensional oscillation more proximally. The conversion of the two-dimensional bending couple to the three-dimensional spiralization is brought about by the spread or diffusion of the contraction stimulus through the cytoplasmic 'matrix' and would be facilitated, and possibly directed[9], by sub-fibrillar connexions if they should be shown to exist. The point that bears emphasis, however, is the suggestion that the same propagated disturbance may result in a two-dimensional vibration proximally and a three-dimensional spiral distally. In this respect, a torsional wave always accompanies the bending wave. Any decrease in the resistance or compressibility of the distal region of the tail would tend to increase the three-dimensional lashing of that portion of the flagellum.

OBITUARY

Prof. Lewis Knudson

THE death occurred on August 31 of Prof. Lewis Knudson, emeritus professor of botany in Cornell University, Ithaca, New York. Thus ended an association with the New York State College of Agriculture at Cornell University which was in its fifty-first year.

Prof. Knudson was widely known for his work on the aseptic culture of orchid embryos, and his death will be regretted by botanists and plant physiologists around the world. Since his retirement from active teaching and administrative duties in 1952, at the age of sixty-eight, Prof. Knudson had retained his interest in his research, and, until a very short time before his death at the age of seventy-three, he daily visited the office and laboratory in which he continued to work. He is survived by his wife, two sons and several grandchildren.

The career of Prof. Knudson spans the history of plant physiology in the College of Agriculture at Cornell University, for in 1908 he came from the University of Missouri to work with Prof. Duggar in the then newly established Department of Plant Physiology. Dr. Knudson was to pass his entire and long career at Cornell University, from 1911 when he was awarded the Ph.D. degree, to 1916 when he became professor of botany in the newly constituted Department of Botany under Prof. K. M. Wiegand, to 1941 when he assumed the role of administrative head of the Department on the death of Prof. Wiegand, and until his retirement in 1952.

During 1919–21 Dr. Knudson spent a year in France, carrying out work at the Sorbonne, attending lectures at the Pasteur Institute, and he also gave lectures in Madrid and Barcelona. His interest in the problems of tropical agriculture took him many times to the countries of Central America.

The effect of the early formative years with Prof. Duggar was long evident and often referred to by Dr. Knudson, even in his later years. An early interest in fungi and in aseptic techniques permeated Prof. Knudson's pioneer work on the growth of whole plants under aseptic conditions, which in turn made feasible his early studies of their organic nutrition and the availability of various carbohydrates for growth. It also permeated his early influence on the growth of excised roots, his work on nitrogen fixation and the nodule-forming organisms, his studies on the germination and nutrition of orchid embryos, and his well-known investigations on mycorrhiza and the aseptic growth of plants which were previously regarded as essentially requiring the mycorrhizal fungus. Prof. Knudson's uses of both orchid embryos and *Chlorella* to study the facts of mineral nutrition are well known. This dominating interest in the use of aseptic culture methods in the study of plant physiological problems, or to study means of suppressing the growth of fungi as pathogens, survived to his death, for in this area of work his advice was continually being sought by industry. Although tissue culture procedures are now commonplace, and the use of uni-algal cultures is frequent in many types of physiological work, one has to recall that Prof. Knudson was among the earliest pioneers in the adoption of these methods. Less widely known, but still noteworthy, was Prof. Knudson's interest in the effects of radiation on chloroplast morphology in ferns.

Another salient characteristic of Prof. Knudson's work and interest was that he was always challenged by the research opportunities inherent in situations fraught with economic consequences. Among his earliest work was an investigation of fermentation processes in the difficult area of tannins ; he was challenged by, and often referred to, the commercial production of vanilla ; and even up to his death he was working upon a summarized account of the Panama disease of the Gros Michel banana in Central America, a problem to which he had devoted many years. Often far ahead of his time, many of Prof. Knudson's works paved the way so that later researches, made after knowledge and technique had advanced, flourished in areas that he had pioneered.

Perhaps best known for his work on the germination and growth of orchids, Dr. Knudson had a wide circle of correspondents. He advised many growers in his aseptic culture methods of raising embryos to whole plants. One correspondent, not known to him personally, touched him deeply in his later years when he acknowledged his work on orchids by sending an exact replica of an orchid flower set in silver. In 1956, the Federated Garden Clubs of New York State awarded to Dr. Knudson their Gold Medal, which had previously been awarded only to the distinguished botanist and horticulturalist and Dean of the College of Agriculture, Liberty Hyde Bailey.

Prof. Knudson's many friends and students, and those in science and industry who knew of his work, will deeply regret the termination of his long career as botanist and especially plant physiologist.

F. C. STEWARD

NEWS and VIEWS

Royal Scottish Museum: Dr. A. C. Stephen

Dr. A. C. Stephen, who is retiring from the post of keeper of the Department of Natural History in the Royal Scottish Museum, Edinburgh, was educated at the Edinburgh Institution (Melville College), Robert Gordon's College and the University of Aberdeen. He interrupted his studies to serve with the Royal Engineers in France and Belgium. For the last year of the First World War he worked as an assistant in the Department of Chemistry, Royal College of Science, London, on new poison gases and other problems. Returning to Aberdeen, he graduated with distinction in zoology, and for the next year acted as an assistant in the Chemistry Department, North of Scotland Agricultural College, Aberdeen. In 1920 he joined the scientific staff of the then Fishery Board for Scotland. Spending much time at sea, where during intervals in general duties he carried on a quantitative investigation of the bottom fauna of the North Sea with the newly designed Peterson grab, he later extended the survey to the sandy and muddy intertidal areas, investigating numerous portions of the Scottish coast. In 1925 he joined the staff of the Natural History Department of the Royal Scottish Museum, as assistant. He was appointed assistant-keeper in 1934 and keeper in 1935. He graduated D.Sc. in 1934. Besides papers on the intertidal and offshore surveys, he has published accounts of the turtles, cephalopods and Gephyrea of Scottish waters. He has also published accounts of the Gephyrea from many parts of the world, being a recognized authority on this group. As keeper, his principal task has been the care of the collections during the Second World War and the rehabilitation of the Department after the War. For a period he was also in charge of the Geology Department. Apart from his work in the Museum, he has taken part in outside scientific activities. He has been twice president of the Astronomical Society of Edinburgh, secretary and president of the Royal Physical Society of Edinburgh, a member of several councils and committees. During 1935–39 he was editor of the *Scottish Naturalist*. He also acted for a period as an examiner for the Museums Diploma.

Mr. A. R. Waterston, O.B.E.

Mr. A. Rodger Waterston, who is to succeed Dr. Stephen as keeper of the Department of Natural History in the Royal Scottish Museum, was educated at St. Paul's School, London, and the University of Edinburgh, where he graduated in June 1934 with first-class honours in zoology. He was awarded the Sir David Baxter scholarship in natural science and joined the staff of the Royal Scottish Museum as assistant keeper in the Department of Natural History in September 1935. On the outbreak of the Second World War he was seconded to the Ministry of War Transport and was District Transport Officer for Clydeside until 1942. After a year's service in the Royal Scots, he was transferred to the Middle East Supply Centre, Cairo, as locust officer in the Middle East Anti-Locust Unit, and took charge of the Palestine Anti-Locust Unit in Saudi Arabia. During 1945–46 he paid two visits to the Yemen to establish friendly relations and to introduce modern anti-locust campaigns there. He became chief locust officer of the Middle East Anti-Locust Unit in 1947, and from then until 1952 he was entomological adviser to the British Middle East Office and attaché for scientific affairs at the British Embassy, Cairo. His work was largely concerned with the building up of international technical co-operation and co-ordination of desert locust control work between the countries of the Middle East, Africa and India. He was made O.B.E. in 1952 in recognition of his contribution to anti-locust work in the international field. He resumed duties in the Department of Natural History at the Royal Scottish Museum in the autumn of 1952 and has since been engaged in the reorganization of the insect collections.

Royal Society: Officers

At the anniversary meeting of the Royal Society on December 1, Sir Cyril Hinshelwood was re-elected president. The other officers re-elected for the ensuing year were: *Treasurer*, Sir William Penney, director of the Atomic Weapons Research Establishment, Aldermaston; *Biological Secretary*, Sir Lindor Brown, Jodrell professor of physiology at University College, London; *Physical Secretary*, Prof. W. V. D. Hodge, Lowndean professor of astronomy and geometry in the University of Cambridge; and *Foreign Secretary*, Dr. H. G. Thornton, lately head of the Department of Soil Microbiology at Rothamsted Experimental Station. Other members of Council elected were: Dr. G. E. R. Deacon, director of the National Institute of Oceanography, Wormley; Sir Charles Dodds, Courtauld professor of biochemistry, University of London; Prof. G. Gee, Sir Samuel Hall professor of chemistry, University of Manchester; Dr. H. Godwin, reader in Quaternary research, University of Cambridge; Prof. L. Hawkes, emeritus professor of geology, Bedford College, University of London; Prof. R. D. Haworth, Firth professor of chemistry, University of Sheffield; Sir Christopher Hinton, chairman of the Central Electricity Generating Board; Prof. A. L. Hodgkin, Royal Society research professor; Prof. N. Kemmer, Tait professor of natural philosophy, University of Edinburgh; Prof. M. J. Lighthill, Beyer professor of applied mathematics, University of Manchester; Prof. D. M. Newitt, Courtauld professor of chemical engineering, Imperial College of Science and Technology; Prof. G. Pontecorvo, professor of genetics, University of Glasgow; Prof. R. J. Pumphrey, Derby professor of zoology, University of Liverpool; Prof. H. W. B. Skinner, Lyon Jones professor of physics, University of Liverpool; Prof. Wilson Smith, professor of bacteriology, University College Hospital Medical School, University of London; Prof. J. Z. Young, professor of anatomy, University College, London.

Royal Society and Nuffield Foundation Commonwealth Bursaries

Awards under the Royal Society and Nuffield Foundation Commonwealth Bursaries scheme have been made as follows: Dr. I. R. C. Bick, senior lecturer in organic chemistry, University of Tasmania, to assist him to visit Cambridge, during June 1959–March 1960, in order to study the latest developments and research techniques in natural products organic chemistry; Mr. E. H. Davis, senior lecturer in civil engineering, University of Sydney, to enable him to study the stress – strain properties of the soil matrix, and the application of the theory of plasticity to soil, at Watford and the Imperial

College of Science and Technology, London, during February–December 1959; Dr. P. R. Davis, lecturer in anatomy, Royal Free Hospital School of Medicine, London, to enable him to extend his studies of African human skeletal material at Khartoum, Ibadan and Makerere, to study fossil primate material at Nairobi and to visit fossiliferous sites, for six months from February 1959; Prof. C. M. Donald, professor of agriculture in the Waite Agricultural Research Institute, University of Adelaide, to enable him to study recent advances and techniques in agronomic research at Hurley and elsewhere in the United Kingdom, for three months from April 1959; Prof. P. C. Dutta, professor of organic chemistry, Indian Association for the Cultivation of Science, Jadavpur, to enable him to gain experience in the field of alicyclic compounds related to terpenoids, at the Imperial College of Science and Technology, London, and Oxford, for about ten months from May 1959; Dr. A. Iggo, lecturer in physiology, University of Edinburgh, to enable him to gain experience of techniques for the analysis of spinal cord activity and to apply these in further investigation of the nature of rhythmic nervous activity in mammals, at Canberra, for about five months from July 1959; Dr. L. N. D. Lucas, senior lecturer in physics, University of Western Australia, to enable him to gain experience in the use of electron microscopy to study the microstructure of solids, at several centres in the United Kingdom, for about ten months from March 1959; Mr. I. L. Mason, of the Agricultural Research Council Unit of Animal Genetics, Edinburgh, to enable him to visit Australia and New Zealand for about ten months in 1959, in order to study animal breeding research there, particularly on beef cattle under tropical and sub-tropical conditions; Dr. Jean M. Tyler, Imperial Chemical Industries Research Fellow, Department of Chemistry, University of Edinburgh, to enable her to carry out structural investigations on West Indian natural products at Kingston, Jamaica, for a year from April 1959; Dr. J. M. Vincent, associate professor of agricultural microbiology, University of Sydney, to enable him to continue his studies of the root-nodule bacteria at Rothamsted, for about eight months during 1959.

The New Humanism of Science

Is science a triumphal march or a stumbling shuffle from one intellectual expedient to another? Mr. Frank Greenaway thinks the latter, and in the *Universities Quarterly* (12, 130, 228, and 13, 24; 1957–8) compares the modern scientist to a caterpillar tractor, perpetually pulling up his support behind him as he goes. The pseudo-literature of experimental reports exfoliating every week hides the real understanding of science, precludes 'eaves dropping' by other educated men and drives fissures into our intellectual society. "It is a curious thing," he writes, "that while most intellectual people are well aware of a sense of tradition in the things they respect as the basis of their culture, they have very little idea of any tradition in science." As he points out, Copernicus, Agricola and Vesalius published their principal works before Shakespeare was born; most music is younger than modern chemistry, and most plays than the discovery of the electron. Going beyond the "New Humanism" of the late George Sarton, Mr. Greenaway remarks that the scientist has been served by fewer and less able biographers than any of his class of creative thinker, and suggests that there is a great field open to writers to rescue the life of science by rescuing the lives of the scientists and so enable their successors to see science apprehended as a unity.

Mr. Greenaway's closely argued, cogent plea for the restoration of the traditional element in modern conceptual thinking about science presents it as "one of the keys to the new understanding of science which we need". He looks across the fissure to the arts, where the direct relation between the professional creator and amateur assessor continues. He looks ahead to the time when a good scientist will take the trouble to ensure that his paper will survive. Mr. Greenaway mentions Acton; yet might also have included A. L. Rowse, who, though he wrote "I am not merely uninterested, I am positively anti-scientist. I regard it as essentially a specialist activity for people to take to after they have been educated", and could yet say "still, if I had been told something of the fascinating story of mathematics and the men of genius who built up their body of knowledge it would have been quite different".

Bernice P. Bishop Museum, Honolulu

The annual report of the Bernice P. Bishop Museum for 1957, entitled "Concept of the Pacific" (pp. iv+31. Honolulu, Hawaii: Bernice P. Bishop Museum, 1958), follows, as usual, a rather unorthodox pattern. The Pacific has for long been one of the world's major regions of investigation, and it is rightly emphasized that this immense area of ocean, islands and continental margins has a great degree of unity. The report indicates the manner in which the Museum has taken part in research work in the Pacific area, exhibited displays on present and past activities in the region, and makes the interpretation of a knowledge of the Pacific to the public at large its major objective. The chief effort of the year was the installation of exhibits in the Hall of Pacific Life, which is intended to provide a background of the physical geography and natural history of the area.

Engineering Materials and Design

The present era with its ever-increasing rate of advancement in all fields of technology has brought forth many demands for new and better materials and also a great yield of new materials. These two factors are inter-related, but lack of an up-to-date information service has been a serious drawback for the majority of engineering designers. The object of *Engineering Materials and Design* (1, No. 1; October 1958. Pp. 58. Published monthly. Annual subscription 35*s.*; 5.25 dollars. Single copies 2*s.* 6*d.* London: Heywood and Co., Ltd., 1958) is to bring to engineering designers information of new design and material developments in all branches of engineering. This information will be presented in articles, reports and data sheets prepared by authors with first-hand experience. The first issue contains a selection of articles on widely differing topics ranging from uses of titanium and new developments in polyethylene to the selection of fractional horsepower motors and the organization of a modern drawing office. The data sheets included in this number are concerned with molybdenum, polystyrene and new sandwich-material applications. The layout is clear and in contemporary style. If the present standard is maintained, the periodical will succeed in its object.

Aeroelasticity Surveyed

THE second Lanchester Memorial Lecture, given on November 20 before the Royal Aeronautical Society by Prof. A. R. Collar, of the University of Bristol, was entitled "Aeroelasticity—Retrospect and Prospect". Prof. Collar began with a historical survey, mentioning the investigation of flutter made by Lanchester in 1916 before turning to the pioneer work of Duncan and Frazer, who published a paper on "The Flutter of Aeroplane Wings" (1928), which is still a standard reference. Problems of flutter, wing and tailplane divergence, fuselage bending and control reversal multiplied with the advent of the monoplane and during the intense development period of the Second World War. Prof. Collar reiterated his earlier suggestion that by treating the dynamics of a deformable aircraft, all aeroelastic problems could be solved, and added the ray of hope that electronic computers may soon be able to turn a theoretical possibility into a practical reality. He thought that the important recent developments of flight simulators, ground resonance tests and elastic wind-tunnel models, together with greatly increased industrial interest in aeroelastic problems, would ensure fewer accidents in the future. Prof. Collar stressed the need for a better understanding of the effects of damping, which should suppress but often only aggravates flutter. He also wanted to see better methods for estimating air forces. The future problems of very high-speed flight will present kinetic heating effects liable to distort the slender wing sections to a degree not previously experienced. A powerful analytical treatment will be needed.

Tokyo Observatory Polar Tube

THE determination of the position of the celestial pole is of interest in connexion with the construction of star catalogues, the measurement of the precise values of the astronomical constants of precession, nutation and aberration and the movement of the pole due to geophysical disturbances. The meridian circle has been employed in the past for this kind of work, but the installation of a fixed telescope pointing to the pole has certain advantages, including the use of the same star-field at each observation and the simplified structure leading to less complicated nstrumental errors. This idea was first put into practice at the Poulkovo Observatory near Leningrad, and a similar telescope, which they named a polar tube, has been constructed at the Tokyo Observatory by N. Sekiguchi and J. Matsumoto *Annals Tokyo Astro. Obs.*, 5, 131; 1957; *Pub. Astro. Soc. Japan*, 9, 116; 1957). The objective of diameter 20 cm. has a focal length of 269 cm. The photographic plate is rotated about the optical axis at the sidereal rate so that stars are photographed as point images. An almost plane-parallel glass plate n front of the objective has at its centre a small luminized reflecting surface, inclined to the plate at uch an angle as to cause light from the optical axis f the polar tube to be reflected vertically downwards nto a mercury basin. A pencil of light is led into the ube. Some is reflected from the glass plate to form n image on the photographic plate. Some is reflected rom the reflector, mercury and reflector again and orms a second image, shifted slightly from the first mage. Changes of position of the two images give nformation on the motion of the plate relative to he objective. The plate is exposed twice, for about ve minutes on each occasion, at an interval of five r six hours. Ten tenth-magnitude stars are used. The common point of the two star-fields photographed is, after certain corrections have been applied, the position of the celestial pole at that date. Preliminary observations suggest a probable error of 0·3 second of arc for one observation.

Transformation Characteristics of Direct-hardening Nickel Alloy Steels

A MONOGRAPH entitled "Transformation Characteristics of Direct Hardening Nickel Alloy Steels", recently issued by the Mond Nickel Co., Ltd. (pp. 91. London, 1958), is a revised and enlarged edition of the "Atlas of Isothermal Transformation Diagrams of Nickel Steels" previously published. The information contained in the sixty pages of text and twenty-five pages of diagrams is excellently presented, and the bibliography of eighty-six references adds further to the utility of this little book. In addition to the isothermal diagrams and data on end-quench hardenability previously reproduced, the revised publication incorporates supplementary information in the form of continuous-cooling transformation diagrams. This is of value, since the difficulty of applying isothermal data to practical heat-treatments lies in the fact that it is not possible to assess reliably from isothermal diagrams the extent and type of transformations which may occur during continuous cooling. The diagrams shown are for sections from 1 in. to 6 in. in diameter, quenched in oil. Both smaller and much larger sections are of course used, and other cooling media, but this information will probably prove the most generally useful to the engineer in the treatment and application of steels containing nickel.

Charles Leopold Meyer Award for 1958

THE Société de Chimie Biologique has awarded the Charles Leopold Meyer Award for 1958 jointly to Dr. François Gros of the Institut Pasteur, Paris, and to Prof. Jean Turchini; of the faculty of medicine, Montpellier. This annual award of 500,000 francs is made for research on the nucleic acids. Dr. Gros has worked on the mechanism of action of various antibiotics on bacteria; in particular he has studied how antibiotics modify the degradation and reconstitution of the nucleic acids in the cell. Prof. Turchini has conducted a number of investigations over a period of years, partly in collaboration with Prof. P. Castel and Dr. K. van Kien, using specific staining techniques to localize certain nucleic acids within the cell and to follow their evolution under the microscope.

Paul Instrument Fund Awards

AWARDS of grants by the Paul Instrument Fund Committee have been made as follows: £3,835 to Prof. A. L. Cullen, professor of electrical engineering in the University of Sheffield, for the construction of a detector in which radiation pressure is used to convert a microwave signal to an audio or intermediate frequency; £545 to Dr. R. Feinberg, of the Department of Electrical Engineering, Manchester College of Science and Technology, for the construction of an instrument for measuring the intensity of soft X-radiation generated in experimental high-voltage valves; and £1,000 to Mr. R. M. Sillitto, lecturer in natural philosophy, University of Edinburgh, for the development of a thirty-channel pulse-height analyser, using transistors in place of thermionic valves.

The Paul Instrument Fund Committee, composed of representatives of the Royal Society, the Physical

Society, the Institute of Physics and the Institution of Electrical Engineers, was set up in 1945 "to receive applications from British subjects who are research workers in Great Britain for grants for the design, construction and maintenance of novel, unusual or much improved types of physical instruments and apparatus for investigations in pure or applied physical science".

Simon Memorial Prize

In memory of the late Sir Francis Simon, the Low Temperature Group of the Physical Society has decided to institute a prize to be known as the Simon Memorial Prize, to be awarded for distinguished work in experimental or theoretical low-temperature physics. An appeal for financial support has been made to several industrial firms, and their generous support has already ensured the success of the scheme. However, it is believed that many other organizations and individuals will wish to make small contributions so that the memorial is truly representative of the many who have known and benefited from the life and work of the founder of the Group. The fund will therefore remain open until the annual general meeting of the Group on January 15, and contributions should be sent to the Chairman or Hon. Secretary before that date, addressed to the Low Temperature Group, Physical Society, 1 Lowther Gardens, Prince Consort Road, South Kensington, London, S.W.7.

University News: Glasgow

The U.S. National Institutes of Health have provided a grant of 45,000 dollars for one year, renewable at the rate of 27,000 dollars for each of four successive years, for the expansion of research on human genetics in the Department of Genetics. This has made possible the planning of a concerted attack on the problem of whether genetic analysis in man, and slow-breeding animals and plants, can be based on mitotic segregation in somatic cells. Investigation of this problem, under Prof. G. Pontecorvo, requires initially the combination of research workers with a variety of skills—for example, protein chemists, immunologists, virologists. For this reason, the grant provides not only for equipment, but also for adequate visiting fellowships, which will permit senior workers to join the team for suitable periods. With the installation of the English Electric DEUCE computer at the beginning of this session, the Computing Laboratory has now been established under the direction of Dr. D. C. Gilles; and additional staff, including D. C. Williams as lecturer, has been appointed. Arrangements are being made for a formal opening of the Department in the New Year. The new engineering building at the eastern extremity of the University site is now occupied. A. F. Munro has been appointed senior lecturer in veterinary physiology, and C. G. Elliot, Matthew Holmes and Ian S. Hughes have been appointed to lectureships in agricultural botany, physiology and natural philosophy, respectively. For the present session, 372 new students (284 men and 88 women) have been admitted to the science departments, compared with 351 in 1957. The total of matriculated students in the University as a whole now stands at 6,330.

Qualifications in Mathematics

The Council of the Mathematical Association has set up a sub-committee to consider and report upon the proposal that the Association should establish an examination machinery in mathematics. The underlying principle is that there are many teachers who would wish to improve their academic qualifications but who have neither the time nor the facility to read for an external degree. It is thought that a diploma of efficiency in either or both pure and applied mathematics to the standard of the old ordinary degree might be of value to these men and women and, at the same time, a reward for further study.

Announcements

Prof. A. Salam, professor of applied mathematics in the Imperial College of Science and Technology, London, has been awarded the Hopkins Prize of the Cambridge Philosophical Society for his contribution to the theory of non-conservation of parity in physics. The Prize has been awarded every three years since 1867 for work in mathematical–physical or related fields. The present award relates to the period 1955–57, and is of the value of £80.

The Transactions of the fourth International Congress on Biochemistry, held in Vienna during September 1958, representing all the symposia, colloquia and discussions, will be published in fourteen volumes by the Pergamon Press. These will appear early in 1959.

The British Institution of Radio Engineers announces the formation of a Medical Electronics Group. This is in accordance with the policy of the Council to establish specialist groups to foster the general dissemination of information in the specialized fields of radio and electronic engineering. The chairman of the Group Committee is Mr. W. J. Perkins. There will be five meetings of the Group during the current session. The inaugural meeting will be on January 23, when Prof. A. V. Hill, emeritus professor of physiology in University College, London, will give an address.

The Department of Extra-Mural Studies of the University of London and the Association of Agriculture are holding a course of ten weekly lectures on "Britain's Food Supplies". The lectures will be given weekly at 6.30 p.m., starting on January 14 at the British Institute of Recorded Sound, 38 Russel Square, London, W.C.1.

An International Colloquium on Communication and Language is being organized by the Faculty of Medicine of the University of Paris, with the collaboration of the professor of otorhinolaryngology the Société Française de Phoniatrie, the Laboratory of Physiological Acoustics and the professor o neuro-physiology in the Collège de France. It will be held at the Faculty of Medicine, 45 rue des Saints Pères, Paris 6e, during January 22–25, 1959. Communication and language will be discussed from the point of view of information theory, and the programme will deal with the following aspects of the subject: mathematical and philosophical, physical physiological, pathological, psychological, statistical Further information can be obtained from Dr. B Vallancien, 16 rue Spontini, Paris 16e.

Erratum. In the communication entitled "Alar Polymorphism in the Gerroidea (Hemiptera Heteroptera)", by Dr. R. O. Brinkhurst, in *Nature* o November 22, p. 1461, par. 3, line 11, for "grow" read "row".

SPACE MEDICINE

THE first symposium on space medicine to be held in Great Britain was held at B.M.A. House, London, on October 16 and 17. The symposium was organized by the British Interplanetary Society, and coincided with the twenty-fifth anniversary of its foundation. The symposium was arranged to discuss the reactions of man to the conditions that will be encountered in space and on other planets, and of the equipment that will be required for survival in these hostile environments. Those taking part were research workers in physiology, psychology and human engineering; and the term 'space medicine' embraces the application of these sciences to extra-terrestrial environments.

It is certain that man will travel into space within a few years. His first venture will probably be in orbit, close to the Earth, and lasting a few hours. His second venture will be to the Moon, and his third to one of the planets. Voyages beyond our own solar system are difficult to comprehend, but should not be dismissed too lightly.

The reason for man travelling into space is a controversial subject. Some contend that he merely adds to the complexity of the space vehicle; others that he will earn his keep by taking decisions, particularly in the event of an unforseen emergency. The fact remains, however, that he will go, and that he will be faced with many of the problems discussed at the symposium.

The chairman of the British Interplanetary Society, Dr. L. R. Shepherd, opened the conference with a brief review of the major problems facing man in space, seen from the point of view of a physicist. Over the course of two days, fourteen papers were delivered, and covered fairly well the salient problems of space medicine.

The major physiological difference between travel in a space vehicle and some Earth-bound vehicle such as a submarine is the absence of the gravitational force. Dr. M. P. Lansberg, of the National Aeromedical Centre in Holland, discussed in his paper some consequences of weightlessness. In the absence of gravitational clues to position, some disorientation may occur, and motor activities will have to be re-learned. Complete immersion in water produces some of the characteristics of weightlessness, and a true state of free fall can be produced for periods of about half a minute by parabolic flight in an aircraft. It would be unwise to extrapolate from such flights to the condition of prolonged weightlessness because of the stresses which precede the parabolic flight and because of its short duration. Von Braun has proposed that the space vehicle should rotate, providing artificial weight for the occupants at its periphery. There are serious disadvantages to this system. Changes in weight would be experienced after moving closer to the centre of rotation and also when walking in the direction of rotation, or in the opposite direction, at a constant distance from the centre of rotation. Perhaps more serious, movement of the head would cause tilting and turning sensations, with their appropriate reactions, in the wrong planes. This is due to rotation of the semi-circular canals of the ear while under the influence of a centrifugal rather than a gravitational force.

Some disorientation would seem to be inevitable. Sqn. Ldr. T. C. D. Whiteside, of the R.A.F. Institute of Aviation Medicine at Farnborough, emphasized the importance of the oculogravic and oculogyric reflexes, and issued a warning on the possible seriousness of motion sickness.

Flt. Lt. J. C. Guignard, of the R.A.F. Institute of Aviation Medicine, considered that accelerations at multiples of g, lasting for several minutes, to which the astronaut will be exposed during a rocket take-off, are probably acceptable for a man aligned in the correct position. He concentrated on the physiological effects of transient mechanical forces. Noise and vibration levels are high in large rocket vehicles under power. and, during re-entry at orbital velocities, buffeting of a space vehicle would be poorly damped at the fringe of the atmosphere, and might induce vibrations and oscillatory flight patterns of sufficient intensity to prohibit the crew from controlling the descent. In space, there will be no damping, and any vibration must be absorbed by the vehicle and its occupants. Structure-borne oscillations at frequencies below 100 c./s. are a potential cause of discomfort, fatigue and impaired performance; and low-frequency shaking, below 10 c./s. is a serious nuisance and is difficult to isolate. Flt. Lt. Guignard doubted whether man would float about in an orbital space-suit constructing a satellite from its component parts. If he did, the suit or capsule would have to be a massive affair incorporating gyroscopic stabilization to prevent undamped spin or tumble (which might be fatal), and whole-body harness and anti-shock packaging to save him from impact injuries in a collision.

Dr. H. Bjurstedt, of the Laboratory of Aviation and Naval Medicine at Stockholm, described the results of subjecting anæsthetized dogs to prolonged g forces in the head-to-tail direction. He found hypoxæmia in spite of the fact that the animals were hyperventilating and breathing 100 per cent oxygen, and attributed this to disturbances of ventilation and perfusion in the lungs. It was not clear why there was present, also, a marked alkalosis.

Dr. C. J. Clemedson, of the Research Institute for National Defence in Stockholm, considered the relationship between his studies on blast injury in animals and the problem of explosive decompression in a space vehicle.

Commander G. W. Hoover led a team from the U.S. Office of Naval Research. He delivered a paper on the man–machine system in space vehicles. This consisted, in essence, of proposals for an integrated approach by all concerned to the problem of finding out under what conditions a man works most happily and efficiently in a closed vehicle. These conditions would then be specified for the space vehicle.

The American delegation was emphatic in demanding a cabin environment which did not subject the crew to any unnecessary physiological or psychological strain. Dr. G. Pugh, of the Medical Research Council, was also in favour of a comfortable environment, but pointed out that, as in the case of explorers of the past, the demand for reduction in weight and complexity might necessitate exploitation of man's capacity to adapt himself to a wide range of environmental stresses. He discussed the possibility of reducing metabolic rate and of breathing oxygen at low partial pressures to save weight in food and oxygen. Dr. Pugh also made the important point that while lack of preparation had been the undoing of many previous explorations, the ultimate test of performance is in the real situation.

Flt. Lt. J. Billingham, of the R.A.F. Institute of Aviation Medicine, examined the problems of heat exchange between man and the sealed cabin, and proposed a specification for environmental conditions during interplanetary flight. He also presented a paper on heat exchange between man, his pressure suit and the environment on the surface of the Moon.

Dr. K. F. Jackson, of the R.A.F. Institute of Aviation Medicine, read a paper on the impairment of human performance in control. He presented the results of an investigation into the factors affecting performance of the crews of long-range reconnaissance aircraft, with particular reference to fatigue. He also demonstrated a portable version of his multiple tracking test apparatus, which provides measurements of about ten different aspects of performance.

Mr. C. Cunningham, from the Air Ministry, described the effects of sensory impoverishment, confinement and deprivation of sleep. If these are allowed to continue unchecked for a number of days, the result is changes in the personality and the intellect, often to a degree where logical thought and action become impossible. His evidence was obtained from experimental work, particularly that of Hebb, and from the experiences of former prisoners. There is no doubt that these factors will be of paramount importance in space travel, especially in the case of journeys lasting for years.

Dr. A. S. Parkes and Dr. Audrey V. Smith, of the National Institute for Medical Research, directed attention in their paper on the transport in space of life in the dried or frozen state to the considerable economy of carrying some of the crew of a space vehicle in a state of suspended animation. They considered, however, that the possibility of freezing man was remote. On the other hand, there should be less difficulty in landing spores and seeds on another planet.

Mr. S. W. F. Hanson, of the Ministry of Agriculture, discussed the very practical problems of feeding during travel in space, and the difficulties in the maintenance of a biological cycle, including plants, for journeys of long duration.

The final speaker was Dr. A. E. Slater, of the British Interplanetary Society, who must take credit for the organization of the symposium. He discussed the hazards to man of the radiation belt revealed by the *Explorer* satellites. A region of intense radiation exists between latitudes 30° N. and 30° S. of the magnetic equator. Singer attributed this belt to protons captured in the Earth's magnetic field, and his theory has received considerable support from the information received from the American rocket *Pioneer*, which showed the radiation to be maximal at an altitude of 5,700 miles. Dr. Slater concluded on an optimistic note, describing a suggestion by Singer that the radiation belt could be mopped up in one year by a satellite some ten metres in diameter travelling in an appropriate orbit. J. BILLINGHAM

CHEMICAL PATHOLOGY OF THE NERVOUS SYSTEM

THE subject of the third International Neurochemical Symposium, which was held in the University of Strasbourg during August 25–29, was "The Chemical Pathology of the Nervous System". Several facets of this ramifying topic were discussed by experts from a number of countries, and as those attending the Symposium were restricted to a comparatively small number (130) there were often vigorous and satisfying discussions. As in previous similar symposia, the main subjects were subdivided so that there could be reviews followed by short individual papers on related topics.

A whole day was devoted to metabolic disorders, and the inborn errors of metabolism received detailed attention from Dr. G. A. Rose (London) and Dr. G. A. Jervis (New York). Dr. Rose described a new form of mental defect characterized by the excretion of arginosuccinic acid, and suggested that mental defect may, in fact, include a large group of metabolic diseases of which 'arginosuccinuria' is one, the biochemical lesion in this condition being the inability to split arginosuccinic acid into arginine and fumaric acid.

In this section, too, there were interesting papers on phenylketonuria and Hartnup's disease (Dr. R. Rodnight, London), and the subject of the cerebral lipidoses was also discussed. In connexion with cerebral lipidoses, Dr. M. Lees (Boston) pointed out that analytical methods suitable for normal brain tissue may not necessarily be applicable to pathological material. It was obvious, too, that much more precise information on the chemical nature of brain gangliosides and sulphatides is desirable if rapid progress is to be made in this field. Dr. H. M. Sinclair (Oxford), reviewing the subject of metabolic disorders of nutritional origin, emphasized the wide variety of dietary substances necessary for the adequate maintenance of a 'normal' nervous system.

Prof. J. M. Cumings (London), in a comprehensive review of the chemical pathology of copper, paid particular attention to the copper protein present in brain tissue and its possible significance. The chemical nature of cerebrocuprein in normal brain and that obtained from the brain of individuals suffering from Wilson's disease (hepatolenticular degeneration) was then discussed by Dr. H. Porter (Boston), who has found a significant difference in the chemical properties and electrophoretic mobilities of the two proteins. Members of the Symposium found this an exciting new observation.

The fact that a considerable number of biochemical investigations have been carried out on demyelination processes was reflected in a number of interesting papers on this topic. A review of demyelination in general was given by Dr. R. D. Adams (Boston), and a masterly and concise account of Wallerian degeneration by Prof. R. Rossiter (London, Canada) vividly demonstrated to the audience how precise chemical studies can be used to map a pathological process. Dr. E. Robins's (St. Louis) studies on the biochemistry of chromatolysis in individual anterior horn cells after axonal section illustrated the significance of analysis of individual cells in a heterogeneous system. The importance of developing new techniques in investigations of this kind cannot be overemphasized. Dr. A. Lajtha (New York) presented isotopic evidence suggesting that protein synthesis occurs continuously in the nerve cell body and that there is a flow of protein down the axon. Nissl granules, which are apparently essential for protein synthesis, are absent from the axon.

In a survey based largely on his own experimental observations, Dr. K. A. C. Elliot (Montreal) discussed the problem of swelling and shrinkage in nervous tissue. This was supplemented by Prof. E. W. Dempsey's (St. Louis) account of electron microscopic studies on nervous tissue. He informed the audience that there is an interstitial space in brain tissue which is not negligible. The uptake of fluid into oligodendroglial cells is one way in which swelling can take place.

Under the broad heading of "The Chemistry of Convulsive States and Allied Disorders" there were a number of reports on the significance of γ-aminobutyric acid, glutamic acid and glutamine in brain tissue. For some years the relatively high concentration of these three substances has aroused interest, and further investigations have now been stimulated by the finding that 'Factor I' activity is intrinsically associated with γ-aminobutyric acid. Glutamic acid and γ-aminobutyric acid appear to have opposite effects in brain tissue, and Dr. E. Roberts (Duarte) remarked that the relative levels of glutamic acid and γ-aminobutyric acid may be determined by the intracellular *p*H.

Prof. H. McIlwain (London) gave an interesting discourse on some of his more recent studies on the electrical stimulation of isolated brain tissue. He has found that the subcortical white matter gives a much better response to localized stimulation on the surface than does grey matter, suggesting that the response is transmitted through the white matter. In further experiments Prof. McIlwain has also succeeded, for the first time, in obtaining resting potentials from isolated white matter.

The last two days of the meeting were devoted to the biochemistry of mental disease, in which a considerable amount of research is now being carried out. Dr. A. Pope (Waverley) impressed everyone with his account of the distribution of certain enzymes in various cellular layers of the isocortex of normal and psychotic subjects. Biopsy material from leucotomy operations was used, and the studies may well be unique in that, with the increasing use of tranquillizing drugs, the number of leucotomy operations is being rapidly reduced, cutting off the source of material. In the event, there did not appear to be any specific difference between the enzyme distribution in normal and psychotic individuals so far as the isocortex is concerned.

Dr. M. Reiss (New York) reviewed the importance of hormone studies in mental disease and the value of considering the human organism as a whole. Carbohydrate metabolism in mental disease was reviewed by Dr. H. E. Himwich (Galesburg) with special reference to blood-sugar tolerance curves. Dr. Himwich also discussed whether or not the psychotic individual responds to biochemical stress in the same way that the normal does. The problem of glucose utilization by schizophrenics was discussed by Dr. M. D. Altschule (Waverley), who suggested a direct relationship between the mental state of the individual and the capacity to metabolize carbohydrate. Several members of the audience disagreed with this observation.

In a survey of the relationship between protein metabolism and mental disease, Dr. D. Richter (Cardiff) emphasized the great lack of basic knowledge on the nature of the proteins of the central nervous system. No protein had been well characterized to date, and until this was done progress would be slow, although some advances had been made by electrophoretic methods. It was obvious that the infinite possible variations in the structure of proteins could well be of significance in the nervous system, and different proteins appeared to exist in different parts of the brain. Dr. Richter also pointed out that in many mental disorders there was evidence of developmental failure which might be related to deficiencies in protein metabolism. For example, the mongol brain had an 'unfinished' appearance, while epileptic seizures might be considered to represent a persistence of embryonic convulsions. Furthermore, the fact that twenty-five per cent of all schizophrenic symptoms commenced in the period from 15 to 25 years of age, suggests a relationship between the disease and maturation changes.

If knowledge on brain protein metabolism is scanty, the same cannot be said for the metabolism of amines. A vast amount of research is now under way on the metabolism of amines and their pharmacological effects. Thus it is becoming hard to keep abreast of the large number of published studies on 5-hydroxytryptamine. In his review on the metabolism of amines in mental disease, Dr. E. A. Zeller (Chicago) stated that chromatograms of the amines present in the urines of normal subjects showed that more than thirty different amines could be detected. The urines of schizophrenics gave a different pattern; but very few of the amines had been identified. Prof. H. Waelsch (New York) gave an account of some new results from his laboratory which showed that *in vitro* certain liver protein fractions can take up amines labelled with carbon-14 in covalent linkage, the amine displacing ammonia, probably from the ε-amino group of lysine. The possibility that amines might form modified proteins in this way provoked a long discussion. Some fresh experiments on epinephrine metabolism were then presented by Dr. J. Axelrod (Bethesda), who stated that the formation of adrenochrome is a most unlikely step in epinephrine catabolism. In support of this he has now shown that the major metabolite of epinephrine labelled with tritium is a methylated compound (metanephrine). An enzyme capable of methylating epinephrine is apparently widely distributed. Interesting papers by Dr. T. L. Sourkes (Montreal) and Dr. H. Weil-Malherbe (Washington), on the urinary excretion of catecholamines by psychotic individuals, underlined the current interest in aberrations of amine metabolism.

In a closing speech Dr. S. S. Kety (Bethesda) analysed theories of the biochemical etiology of mental disease. In a satisfying and illuminating way he reviewed the work of those investigators who have concluded that this or that toxic substance, or group of substances, is characteristic of mental disorder, and his conclusion was that no one has convincingly demonstrated a biochemical lesion characteristic of the psychoses. The recent studies on ceruloplasmin, thought to be present in increased amounts in schizophrenic plasma, have proved to be incorrect, while the reports on taraxein, a toxic factor from schizophrenic blood, have proved equivocal. Dr. Kety affirmed that it was most difficult to plan experiments to compare psychotics with normal controls. To obtain proper controls was a considerable feat in itself, and most research had been carried out on patients in institutions who had, among other things, been on an unusual diet. This latter consideration often accounted for reports of the atypical urinary constituents of mental patients. The subconscious desire on the part of the investigator to eliminate conflicting data had also to be overcome. There was considerable discussion after Dr. Kety's paper on the problems inherent in undertaking biochemical studies in mental disease, and one or two speakers put in a plea for investigators to publish negative findings, if only to eliminate duplication of effort.

Altogether the Strasbourg conference was a stimulating experience and thanks are due to the organizing committee for the first-class presentation. All members of the Symposium are indebted also to Prof. Mandel and the Comité de Patronage for the hospitality shown in Strasbourg, and no one will easily forget the many social events organized for the delight of members, especially the outing to Obernai.

G. B. Ansell

HUMAN AND ANIMAL MYCOLOGY

THE International Society for Human and Animal Mycology met in Lisbon during September 5–10. The meeting, the first since the Society was founded in Paris in 1954, was held by permission of the President and General Secretary of the Sixth International Congresses on Tropical Medicine and Malaria. It was attended by more than sixty members of the Society, and twenty-one countries, including the U.S.S.R., Japan, the United States, Brazil, South Africa and Australia, were represented.

Three of the sessions on tropical medicine were devoted to mycotic infections, and these covered the clinical and epidemiological aspects of mycoses, the ecology and saprophytic occurrence of pathogenic fungi and the biochemistry and physiology of pathogenic fungi. In addition, the Society held two business meetings and three paper-reading sessions. Altogether there were more than forty communications, and ample time was allowed for discussion.

In a brief report of the proceedings it is difficult to select, from the many papers presented, those most worthy of note. However, no account would be complete without reference to the contributions on the ecology of pathogenic fungi. Dr. C. W. Emmons (United States) pointed out that, for many of the mycoses, we know that saprophytic growths provide the inocula from which man and animals are infected, and that all epidemiological evidence suggests the probability of saprophytic sources of inocula for a number of other mycoses. He suggested that attempts to isolate the fungi from soil of areas where the specific mycoses are endemic, and a more careful comparison of certain rare pathogens with fungi already described in the literature of general mycology may well increase or complete the list of pathogens with known saprophytic sources. Dr. Emmons said that most of the pathogens of man have a wide geographical distribution and their local distribution is dependent upon ecological factors only partially recognized.

The results of a four-year study of *Coccidioides immitis* in the soil of the South-West Joaquin Valley of California were given by Dr. Egeberg (United States). He discussed the ecological and epidemiological significance of the recovery-rate of the fungus being highest in surface soil three to four weeks after the end of the rainy season, most consistent from the walls of animal burrows, and lowest from the surface towards the end of the dry season when the incidence of the disease is at its highest.

Dr. P. Abbot (Britain), in his consideration of mycetoma, noted that for this disease the incidence is apparently correlated with climatic conditions rather than with specific soil types or other factors. The recovery of the dermatophytes *Microsporum canis*, *M. gypseum* and the non-pathogenic keratinophilic fungi *Trichophyton terrestre*, which is a new species, and *Keratinomyces ajelloi* from the soil of Australia and New Guinea was discussed by Dr. E. B. Durie (Australia), who also reviewed previous work on the ecology of dermatophytes. In his consideration of the mouth as a reservoir of pathogenic fungi, Dr. G. C. Ainsworth (Britain) pointed out that of the many and diverse fungi recorded from the mouth, most are 'contaminants' and only a small number may be considered as 'inhabitants'. Some of the 'inhabitants' appear to provide a reservoir of infection for such endogenous diseases as candidiasis and actinomycosis. A single isolation of *Cryptococcus neoformans* from a healthy horse, during his investigations into the intestinal yeast flora of man and domestic animals, was reported by Dr. N. Van Uden (Portugal). This pathogenic yeast has been shown in the United States to be frequently associated with pigeon droppings, and Dr. K. Ishida (Japan) reported similar findings in Tokyo.

Histoplasmosis was the subject of a number of contributions. The first occurrence of this disease in Japan was reported by Dr. H. Yamato, and a paper on the distribution of histoplasmosis in South Africa was given by Dr. H. I. Lurie. Dr. E. Drouhet (France) and Dr. J. Schwarz (United States) both reported that in culture there is no apparent difference between *Histoplasma duboisii*, first described by Vanbreuseghem in 1952, and *H. capsulatum*. However, the geographical distribution and the clinical and pathological aspects of African histoplasmosis caused by *H. duboisii* differ considerably from the classic form of the disease caused by *H. capsulatum*, and it was generally agreed that for the present it is useful to consider them separately.

In an interesting communication Dr. A. C. Batista (Brazil) stated that from the results of investigations carried out in Brazil it is clear that fungi such as *Candida* and *Torulopsis* may be a primary cause of cholecystitis. Dr. C. S. da Silva Lacaz (Brazil) gave an excellent account of the clinical and epidemiological aspects of the serious mycoses in South America and also showed a most interesting film which he had made on South American blastomycosis.

The importance of therapy was not overlooked. Dr. M. Muftic (Iraq) reported on trials of mycostatin (nystatin) derivatives used intravenously and intramuscularly for the treatment of coccidioidomycosis, and Dr. J. C. Gentles (Britain) gave an account of experimental work which demonstrated the efficacy of oral treatment with the antibiotic griseofulvin for dermatophyte infections.

The use of serological tests for identification and classification of fungi were considered by Dr. H. Seeliger (Germany) and Dr. T. Tsuchiya (Japan).

The social side of the Congresses in tropical medicine and malaria, in which Society members took part, was well organized, and it would be difficult to speak too highly of the hospitality of our Portuguese hosts. The impressive opening ceremony was held in the National Assembly (Palace of São Bento) under the presidency of His Excellency the President of the Republic of Portugal. Evening visits were arranged to places of interest in Lisbon, such as the *estufa fria* (cool greenhouse) in the Parque Eduardo VII and to palaces and gardens in the neighbouring towns of Sintra and Queluz. On the first Sunday there was an excursion to the University of Coimbra.

During the two business meeetings of the Society it was announced that there are now more than two hundred members, and that it would shortly be possible to begin publication of a journal devoted to human and animal mycology. It was agreed that membership of the Society should be open to all interested in medical and veterinary mycology. The date for the next meeting is to be decided by the executive committee: *President*, J. E. Mackinnon (Uruguay); *Vice-Presidents*, G. C. Ainsworth (Britain); C. W. Emmons (U.S.A.); P. Negroni (Argentine); G. Segretain (France); *General Secretary*, R. Vanbreuseghem (Institut de Médecine Tropicale, 155 rue Nationale, Antwerp). J. C. GENTLES

STUDENT APPRENTICESHIP IN ELECTRICAL ENGINEERING

STUDENT apprenticeship is the subject of a report* published recently by the Institution of Electrical Engineers. The report is the work of a joint committee, under the chairmanship of Sir Willis Jackson, appointed by the Council of the Institution in consultation with the Council of the British Electrical and Allied Manufacturers Association, the Radio Industry Council and other interested bodies.

It is stated in the foreword that the report aims to do two things: first, to explain to teachers, senior pupils and parents the scope of the educational requirements and the training envisaged in student apprenticeship for electrical engineering; and secondly, to give guidance to those responsible for the education and training of student apprentices as to the structure and content of academic courses and practical training.

Graduate apprenticeship and student apprenticeship are the two main avenues leading to professional qualification in electrical engineering in Britain. A university graduate, on completion of his three- or four-year full-time course of study, will normally undertake a two-year apprenticeship with a manufacturing or operating organization. The student apprentice, on the other hand, enters industry from school and pursues academic study more or less in parallel with his practical training throughout a period of five or more years. Study and practical experience can be interleaved in a wide variety of ways, but one pattern which has evolved and which shows increasing practical importance is that of the sandwich course of five years duration, in which four six-month periods of full-time study are interposed between five equal periods of practical experience in industry. Recruitment to a scheme of student apprenticeship should take place normally at about the age of eighteen, the candidate having pursued sixth-form work at school and having obtained passes in mathematics and physics at Advanced Level together with five or more passes in suitable subjects at Ordinary Level of the General Certificate of Education. There is, however, provision for entry from the National Certificate course, the requirement being a 'good' Ordinary National Certificate. Thus, the boy who has left school early and has embarked upon craft or technician training is not debarred from entering upon the professional course provided that his studies have shown sufficient promise.

The successful completion of a sandwich course will normally qualify for a recognized award such as that of the recently established Dip.Tech.(Eng.) or of a college diploma. It must be emphasized that a distinctive feature of the sandwich course is the association of the industrial experience with the academic study as an integral part of the course, it being a requirement that the student should have completed his practical training satisfactorily as well as his examinations before the award is granted.

Sandwich courses are normally 'industry based', that is to say, the student is recruited by an industrial organization as a student apprentice and the firm takes responsibility for the complete planning of his industrial experience throughout the five six-month periods which he will spend in the works. This arrangement works well with large organizations within which the whole range of experience required by the apprentice can be obtained. The position of smaller firms may be less satisfactory, as an individual concern may be able to provide excellent training covering a part of the requirement but be completely deficient in respect of other portions. This difficulty is being met by group training schemes in which a number of concerns co-operate in providing full professional training facilities, and the group, in fact, accepts a collective responsibility towards the apprentices of the individual concern.

As an alternative to the 'industry based' sandwich course there is provision for 'college based' courses in which the college accepts the student and makes suitable arrangements with one or more firms to provide the full practical training required. The report emphasizes that the success of a 'college based' scheme is dependent upon the practical training being planned in conjunction with a number of firms which will undertake, as in the group training scheme, to provide, among them, for all the aspects of the full practical training. Sandwich courses represent a partnership between college and industry, and this partnership is expressed not only in administrative matters but also in the detailed co-ordination of academic and practical work. There should be close consultation between the college and the industrial firm in the planning of syllabuses for both lecture and laboratory courses. In the final year of sandwich courses it is customary for the student to carry out a fairly extensive individual investigation or special project. The report mentions that the project may well be related to the branch of industry in which the student is engaged and that its completion may sometimes be carried out in the industrial organization during the concluding phase of the student's practical training.

---

* The Education and Training of Student Apprentices in Electrical Engineering: a Report of the Joint Committee on Practical Training in the Electrical Engineering Industry. Pp. 26. (London: Institution of Electrical Engineers, 1958.) 2s.

The teaching staff of the college should keep in close touch with the industrial firm by means of visits and discussions in order to ensure the proper co-ordination of practical training with studies and the maintenance of contact with students during practical training periods. It is suggested that while in the works the student should do a certain amount of directed reading with the view of widening his horizon. The history of engineering and the philosophy of science should find a place among other cultural subjects.

Sections of the report deal in outline with the education and the practical training which is expected of the professional electrical engineer, and two interesting summaries are given of the principal aims. That these are much more than mere statements of subjects to be studied and of skills to be acquired may be illustrated by two quotations. One of the items under the heading "Education" is, "to develop an understanding of the experimental method, its uses and limitations, together with a degree of skill and confidence in carrying out tests and drawing valid conclusions from the observations made", while one of the qualities which his practical training should help the electrical engineer to acquire is the "understanding of the human problems which arise in an industrial community".

Although the report emphasizes that the main route to professional qualification by student apprenticeship should, in the future, be the sandwich course, mention is made of the pursuit of Higher National Certificate courses on the basis of 'day release'. It is pointed out that the Higher National Certificate and endorsements no longer meet the educational requirements of the Institution of Electrical Engineers and two further years of part-time study are required to enable a man to sit for Part 3 of the Institution's examination or, alternatively, a special full-time course of six months duration.

The report concludes with a short section dealing with various administrative matters and an appendix summarizing the relevant regulations of the Institution of Electrical Engineers.

This publication, which, strictly speaking, is a guide to student apprenticeship, is in fact an admirable short treatise on electrical engineering as a career and the means of entering upon it. The report should be in the hands of all concerned with the education of young people. J. GREIG

THE NATIONAL PHYSICAL LABORATORY

REPORT FOR 1957

THE annual report for 1957 of the National Physical Laboratory, Teddington*, includes the report of the Executive Committee which was presented to the General Board at its meeting on May 15, 1958, the second of the annual open days of the Laboratory (see *Nature*, 182, 10 ; 1958) ; detailed reports, prepared by the respective superintendents, of the work of the nine scientific Divisions and the Test House of the Laboratory ; and, for the first time, a separate section devoted to the administration of the Laboratory and general matters.

During the year under review, the report states, the Executive Committee was mainly concerned with matters of long-term policy, particularly with proposals for the quinquennium 1959–64. Some of the recommendations have already been announced and implemented ; for example, the reorganization of the Electricity, Metrology and Physics Divisions. They are to be replaced by three new Divisions, entitled Standards (based on the Metrology Division and responsible for the fundamental standards), Applied Physics (covering secondary standards, electrotechnics, acoustics and radiology, and including the Test House), and Basic Physics (responsible for pioneering developments in non-nuclear physics of potential value to industry). New developments in most of the other divisions, including increases in their staffs, are also recommended. A new section on theoretical physics is advocated for the Mathematics Division. The Control Mechanisms and Electronics Division is encouraged to depart from the design and construction of computers and to study means of replacing, by machines, human faculties other than the ability to count. The Executive Committee is in agreement with the views of the committee set up under the chairmanship of Prof. N. F. Mott to consider the functions of the Metallurgy Division, namely, that the Division be expanded and be provided with a new building properly equipped for the mechanical working of difficult materials, though it considered that its resources should be concentrated upon a limited number of basic researches of current importance. An increase in the number of research fellowships tenable at the Laboratory, and greater flexibility in the staffing arrangements, including more temporary appointments and freedom to appoint senior men at the level appropriate to their qualifications and value to the Laboratory, would be, in the opinion of the Committee, of great benefit to the Laboratory.

---

* Department of Scientific and Industrial Research. Report of the National Physical Laboratory for the year 1957. Pp. viii+122+8 plates. (London: H.M. Stationery Office 1958.) 6s. 6d. net.

The eighth in the series of international symposia, dealing with visual problems of colour, was held at the Laboratory during September 23–25. The proceedings of the symposium on the direction of research establishments which was held in September 1956; two booklets, Nos. 16 and 18, in the series "Notes on Applied Science"; and the first volume, "The Use and Construction of Mathematical Tables", in the new series entitled "NPL Mathematical Tables", were published during the year. In addition to visits to the Laboratory by numerous scientists from many countries, including two Russian parties interested in thermodynamics and the properties of steel and a group of Chinese scientists forming part of a trade delegation, the Parliamentary and Scientific Committee visited the Laboratory to see some of its work and to discuss its organization.

The Laboratory provided a number of items for inclusion in the stands of the Department of Scientific and Industrial Research at the Physical Society Exhibition of scientific apparatus, the Plastics Exhibition and the Engineering, Marine, Welding and Nuclear Energy Exhibition, and displays were shown at the Royal Society soirées and at the Geological Society of London. Seventy-two visits overseas were made by members of the staff, consisting of nine to the United States and Canada, three to Australia and the remainder to Europe.

A long-standing need at the Laboratory is a centre incorporating a first-class lecture hall, restaurant facilities and library, and it is therefore pleasant to read in the report that planning has begun for the conversion of the duplex wind tunnel building into such a centre. The first phase of the conversion will provide a lecture hall, restaurant and cafeteria, conference rooms and an exhibition hall, and the second phase possibly the rehousing of the library. The building work in connexion with the new Ship Hydrodynamics Laboratory at Feltham is proceeding satisfactorily, and that Laboratory should be in full operation by late 1959. A new workshop and a drawing office have been provided for the Aerodynamics Division, and an extension has been made to the control mechanisms building of the Control Mechanisms and Electronics Division.

The recent and more interesting activities of the various sections of the Laboratory are always illustrated and displayed during the open days, and the detailed descriptions of these given in the reports already published in *Nature* (180, 166; 1957; and 182, 10; 1958) make superfluous any additional reference to the substance of the superintendents' reports contained in the annual report. The reports, however, are well worth close study, as they indicate most clearly the very wide range of extremely careful and accurate investigations, relating to both fundamental and applied research, undertaken by the Laboratory. A bibliographical list of publications by members of the staff of the appropriate division accompanies each report. S. WEINTROUB

FIRE RESEARCH

FOR some years now, Britain has occupied a leading position in the conduct of research into fire and explosion. This is no less than is to be expected, for not only are these matters of domestic concern, but also, by reason of the world-wide nature of British insurance, there is little that happens elsewhere that is of no material interest to us.

An important stage was reached in the 1930's when the Riverdale Committee, reviewing fire brigade services in England and Wales, recommended the establishment of a Fire Prevention Research Board by the Department of Scientific and Industrial Research. Only the first practical steps had been taken when the Second World War began.

War-time experience soon showed that in air raids, damage due to fire can greatly exceed in extent that due to high-explosive bombs. For this reason, war-time fire research was developed and conducted under the ægis of the Ministry of Home Security, and a considerable number of internal and extra-mural projects were organized and brought to successful issue. After the War, the Department of Scientific and Industrial Research again assumed responsibility for fire research, and in November 1946 established, now in partnership with the Fire Offices' Committee, representing the insurance companies, the Fire Research Board and the Joint Fire Research Organization. The Fire Offices' Committee placed at the disposal of the organization its Fire Testing Station at Boreham Wood, which had been established in 1935, and this became the site of the new research station. Additional facilities, some of a temporary nature, have been acquired, and final plans for permanent buildings are now far advanced.

One further development should be mentioned. In 1955 the Fire Research Board set up a Committee on Industrial Fires and Explosions to advise with regard to research upon problems encountered by the Factory Inspectorate and others in contact with industry. This step was associated with a very desirable broadening of the interests of the organization into the field of industrial hazards.

An impression of the growth of the work as a whole is gained by comparing the first report of the Board and the Director, issued in 1947, with that for 1957*, which has recently appeared. In the intervening ten years, both the scope of the work and the staff employed have greatly increased, but it is gratifying to note that the length of the report has not increased proportionately.

The statistics with regard to fires attended by fire brigades in the United Kingdom during 1956 and the preceding years are of popular interest, and provide a background against which much of the other work must be viewed. For this reason it is a little surprising that the figures do not receive more comment in the report itself. They reveal a marked recent increase in the total number of fires; to which increase, fires in the open (grassland, heathland, woodland, embankments, refuse, etc.) have contributed most notably. So far as fires in buildings are concerned, the increase is fairly evenly spread over the different types. The most marked, however, is seen in the "other buildings" category, and, as these account for some 10 per cent of the total building fires, further analysis seems to be desirable. A similar remark applies to the analysis of electrical causes of fire where, although most of the defined categories show that the situation is at least under control, "other apparatus" is responsible for growing numbers of fires. The use of oil-burning appliances in buildings is an increasingly important cause, and attention is directed to this matter in the report, where it is pointed out that a disturbing number of fatalities is associated with fires of this type.

---

* Department of Scientific and Industrial Research and Fire Offices' Committee. Fire Research 1957: Report of Fire Research Board and the Report of the Director of Fire Research. Pp. vi+52+8 plates. (London: H.M. Stationery Office, 1958.) 5*s*. net.

In a review of this character it is impossible to do justice to the considerable amount of excellent experimental work that is recorded. Mention may be made of the continuation of the fruitful investigation of the ignition of solid materials by radiated heat, and the interesting experiments on the correlation of fires in buildings with those in models. Among building materials, ordinary and pre-stressed concrete have received particular attention as to their behaviour in fire; while on the operational side, attempts are being made to put the application of fire detectors and the use of water sprays and foam as extinguishing media on a scientific footing. Work on industrial explosions has been directed particularly to the scope and limitations of explosion reliefs and flame arrestors; and a study has been made of the significance of the readings of commercial explosimeters when applied to vapours of diverse nature. Work on the flammability of fabrics is being directed to the important question of the personal hazard arising from the ignition of clothing and to the development of a relevant test. Several smaller but no less interesting investigations complete the list.

A distinct effort has been made to render this report readable and comprehensible to the general reader, even to the provision of a glossary of the special terms used. Like most Stationery Office publications, it provides excellent value for money, and it is to be hoped that it will be widely read.

J. H. BURGOYNE

ANIMAL LIFE ON WAVE-BEATEN ROCKS

By DR. H. GORVETT

Department of Zoology and Applied Entomology, Imperial College of Science and Technology, London, S.W.7

WAVE-BEATEN rocks on exposed shores appear, at first sight, to be somewhat barren and devoid of life, but recent investigations have shown that here, as in other parts of the sea-shore, there exists a surprisingly large number and variety of animals.

The richness of the microfaunas of intertidal seaweeds and lichens has been amply demonstrated[1]; animal life in rock crevices is known to be both diverse and abundant[2]; and sorting and counting the inhabitants of even a very small rock pool may well keep a dozen students on a marine biology course busy for days. But most of the work done so far on this type of sea-shore ecology has been concerned with relatively sheltered habitats, and it is interesting to discover that the surface of a wave-beaten reef, where conditions would seem to be far less hospitable, may support a microfauna almost equally rich.

The site of the present investigation is a low rocky reef extending seawards from the western shore of the island of Oronsay in Argyllshire. Oronsay is about ten miles west of the island of Jura, and its western coast is exposed to the full force of Atlantic gales. The reef is a smooth hump of rock about 80 yards long and 12 yards wide, rising gently to a flattened crest about 6 ft. above mean low-water springs. Although the conditions here are not as rigorous as in certain other localities in the Western Isles, the degree of exposure is such that few of the larger seaweeds can survive on its surface, and these only as isolated tufts separated by wide expanses of weed-free rock. In place of the luxuriant cover of weed found above low-tide level in more sheltered situations, there are only stunted specimens of the exposed shore form of *Fucus vesiculosus* (*F. vesiculosus* L., f. *linearis* (Huds.), commonly known as f. *evesiculosus*[3]), small compact cushions of the red calcareous weed *Corallina officinalis*, a few individual plants of the thong-weed *Himanthalia elongata*, and occasional small tufts of *Gigartina stellata*. Below low-tide level the rocks are coated with the red calcareous *Lithothamnion*, partly hidden by a relatively prolific fringe of fucoids, in which the species of *Laminaria* (*L. digitata* and *L. hyperborea*) are intermingled with a high proportion of *Alaria esculenta*. The latter is a weed that grows only in relatively exposed situations, and it is the only fucoid capable of withstanding conditions of extreme exposure such as are to be found on the isolated islet of Rockall[4].

The only conspicuous animals on the areas of rock surface between the weed tufts are limpets, patches of barnacles, the anemone *Actinia* (fairly common in pools and crevices), and occasional little clusters of small mussels (also in crevices). The greater part of the animal population, however, has to be searched for more carefully, since it consists of small forms living in the shelter provided by the larger organisms, more especially by the encrusting barnacles and by the cushion-like growths of *Corallina*.

If the barnacles are scraped off the rock and separated from one another under a binocular microscope, and if their skeletal plates are taken apart, a host of small animals is revealed, some living in the empty shells of dead barnacles, others in the chinks and crevices between the plates of living ones. So numerous are these that a scraping from even a small area of rock surface cannot be fully sorted in less than two or three days. The record is held at present by a patch of barnacles from the flat top of the reef about 6 ft. above mean low-water springs. This measured 5 cm. × 5 cm. (2 in. × 2 in.) and was found to contain a total of no less than 1,756 animals. These were all visible to the naked eye, and were picked out individually with forceps. Single-celled animals such as foraminiferans (which were common) were ignored, and so were many smaller members of other groups (such as nematodes). The animals counted belong to more than twenty species and are made up as follows :

Balanus balanoides	97	*Hemioniscus balani*	1
Chthamalus stellatus	55	Amphipoda	9
Turbellaria	2	*Anurida maritima*	6
Nemertinea	3	Chironomid larvæ	66
Nematoda	4	Acarina	1,056
Polychæta	19	*Littorina saxatilis*	191
Oligochæta	55	*L. neritoides*	48
Copepoda	4	*Mytilus* sp.	9
Tanaidacea	8	*Lasaea rubra*	123

The most numerous animals are the mites, of which there appear to be five species. But even if these, and the barnacles themselves, are excluded, there still remain 548 animals of other groups. Totals of more than 800 animals, excluding the barnacles and numerous but uncounted mites and copepods, have been obtained from other 5 cm. × 5 cm. samples. The most surprising animals to find inhabiting the surface of wave-beaten rocks are, perhaps, the chironomid larvæ ; but these are often common in rock pools[5] and in other parts of the shore.

The alga *Corallina officinalis* also harbours a large microfauna. In the pools this weed grows into a loose branching plant several inches high, but on the exposed rock surface it forms compact rounded humps an inch or less in height. Although the branches are short and closely packed, large numbers of small tubicolous polychætes, oligochætes, amphipods, chironomid larvæ, nematodes, and others manage to squeeze into the narrow cavities between the branches for shelter and protection.

The population of small animals appears to be considerably greater on the Oronsay reef than on the islet of Rockall, where only six species of invertebrate animal have been found[6]. But, as Dr. Crisp suggests, additional factors may be involved here, and the paucity of animal life on Rockall may be due not only to the high degree of exposure to which it is subjected but also to the island's small size and isolated position—a combination of conditions that may effectively prevent its being colonized by the settlement of the free-swimming larval stages that are produced by so many of the shore-dwelling animals.

Work is proceeding on a comparative survey of the microfaunas of wave-beaten rocks, and it is hoped that in due course it will be possible to publish elsewhere the results of this work in greater detail.

I am most grateful to Prof. H. R. Hewer for his efficient organization of a combined seal and microfauna expedition to Oronsay, and to the Royal Society for a grant from the Browne Research Fund.

DEPENDENCE OF THE NUCLEONIC COMPONENT OF COSMIC RAY AIR SHOWERS ON RADIUS

By C. S. WALLACE, Dr. M. M. WINN and Dr. K. W. OGILVIE

The F.B.S. Falkiner Nuclear Research and Adolph Basser Computing Laboratories, School of Physics*,
University of Sydney

IN an experiment using a core selector and a neutron-operated detector sensitive to radiations producing small stars in lead, Marsden and Doran[1] have studied the nucleonic component in extensive showers.

A large proportion of the recorded counts of such an apparatus is due to low-energy ($\sim$ 1 BeV.) nucleons, but the thick interacting layer of lead usually used makes an estimate of the mean energy difficult. We shall describe a similar experiment, in which a more complete analysis allows us to give a density distribution of nucleons with radius r from the shower core, and more complete information about processes occurring in the detector.

The Sydney air-shower apparatus[2] allows the size, N, of showers falling within its sensitive area to be found and the positions of their cores to be determined with an accuracy of $\pm$ 4 m., using an assumed structure function and the total particle density at nine points. The direction of approach can also be obtained. To detect nucleons we used the Sydney neutron monitor, a standard International Geophysical Year apparatus of area 1·88 m.^{2}, as described by Simpson[3] which contained eleven counters at the time of the experiment.

The shower master-pulse gates pulses from the monitor into an additional scaler for a period from + 5 μsec. to + 300 μsec. after the shower. The number of neutrons counted in each event is thus recorded. A maximum of fifteen neutrons may be handled in this way, sixteen or more being recorded as a group. The proportion of accidental counts is 1 in 500 showers, and a total of 3,113 showers was observed at various times between June 1957 and May 1958.

In order to produce a recorded count, a nucleon associated with an air shower must traverse the monitor and give rise to an interaction which produces neutrons, which must then be successfully detected. Besides the real density distribution with radius and shower size, the number, energy, and direction of nucleons produced at an interaction, and the detection efficiency for the neutrons among them will be involved. The number of neutrons observed for a shower of given size at a given radius will therefore not be unique but will have a distribution. In order to extract the average density distribution we make the following assumptions :

---

* Also supported by the Nuclear Research Foundation within the University of Sydney.

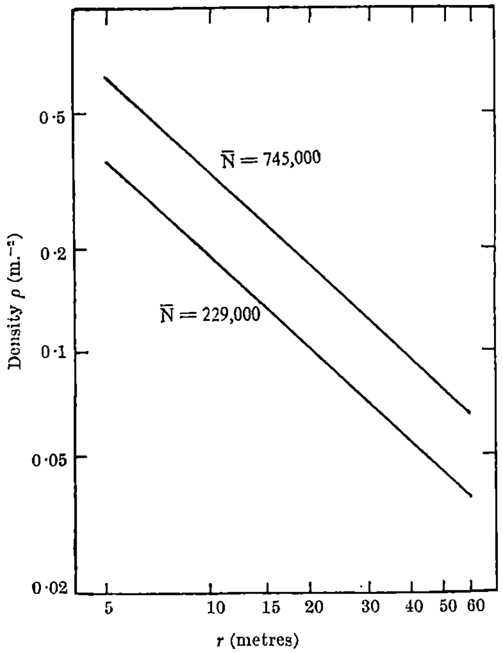

Fig. 1, Uncorrected density of nucleons as a function of r for two values of N, these being the mean values of two of our shower size classes; $2 \cdot 29 \times 10^5$ for $10^5 < N < 4 \times 10^5$ and $7 \cdot 45 \times 10^5$ for $4 \times 10^5 < N < 1 \cdot 6 \times 10^6$

(1) The number, k, of air shower nucleons interacting is a Poisson variable with mean $n(N,r)$. (2) The interaction releases a number of neutrons $M(N,r)$. We are here averaging over the energy distribution of incoming particles. (3) The detection efficiency per neutron p is independent of N and r and is small. The number of recorded counts per interaction is then a Poisson variable of mean m equal to Mp, but this is less true the larger p becomes. Thus for given N and r the probability of recording x counts in an event is :

$$P_x(m,n) = \sum_{k=0}^{\infty} P(k,n)\, P(x,k)$$
$$= \sum \frac{\exp(-n)\, n^k}{k!} \; \frac{\exp(-mk)\,(mk)^x}{x!}$$

Known values of M and p for similar structures[4] lead us to the conclusion that m is of the order of 1. The count frequency may be plotted as a histogram for a given size of shower and radius, Table 1 showing a typical example.

Table 1

No. of counts, x	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	$\geq$ 16
Frequency, a_x	133	25	14	5	4	2	2	2	1	0	0	2	2	0	0	1	2

For each such histogram a likelihood function can be formed :

$$L(m,n) = \prod_{x=0}^{16} \Big[P_x(m,n) \Big]^{a_x}$$

where a_{16} includes events with 16 or more counts and $P_{16}(m,n) = 1 - \sum_{x=0}^{15} P_x(m,n)$.

By maximizing these functions, assuming that m and n depend on some power of the radius and shower size[5], we obtain expressions for m and n valid over the region $10^5 < N < 2 \times 10^6$, 4 m. $< r <$ 60 m. These show the following features :

(1) $m = Mp$ is found to vary as $N^{0 \cdot 15 \pm 0 \cdot 05} / r^{0 \cdot 25 \pm 0 \cdot 05}$. The detection efficiency, p, for the neutrons is unlikely to vary rapidly with the energy of the incident particles. This assumes that most of the neutrons are produced by evaporation, though not necessarily in one interaction, and that their energy is a slowly varying function of the excitation energy[6]. Thus the mean energy of the particles detected decreases slowly with increasing radius and the multiplicity observed means that it is greater than about 500 MeV.

(2) The density of the particles counted is proportional to $N^{0 \cdot 47 \pm 0 \cdot 1}\, r^{-0 \cdot 92 \pm 0 \cdot 1}$ between 5 and 50 m., in fair agreement with Marsden and Doran.

(3) In Table 2 we compare our results with those of Lehane[7]. The densities in the third column are obtained by dividing our value of n for 5×10^5 particle showers at the appropriate radius by the area of the lead in the neutron monitor, and so are not corrected for the fraction of particles going through it without interaction.

Table 2

Radius (m.)	Lehane (m.$^{-2}$)	Uncorrected density (m.$^{-2}$)	Corrected density (m.$^{-2}$)
5	1·5	0·52 ± 0·1	0·79 ± 0·15
10	0·83	0·26 ± 0·05	0·4 ± 0·1
25	0·36	0·147 ± 0·01	0·223 ± 0·015
50	0·047	0·06 ± 0·01	0·09 ± 0·015

Agreement between the corrected readings, obtained by using an interaction mean free path of 184 gm./cm.^{2}, and those of Lehane is fair, but our results show a less rapid decrease with increasing radius. If the mean energy of the nucleons decreases with distance from the shower core, as is suggested by the variation of m with radius, the rate of Lehane's penetrating-particle detector would be more affected than that of our apparatus. A calculation, using the cross-section for production of stars by μ-mesons extrapolated to ground-level[8] and the density of μ-mesons found by Lehane, shows that production of stars by μ-mesons cannot produce this discrepancy. Similarly, production of neutrons by μ-mesons stopping in the lead produces too small an effect, and we regard the most likely explanation to be the sensitivity of the monitor to neutrons with an energy of several MeV., many of which are likely to be scattered to the outer regions of an extensive air shower.

We wish to acknowledge a grant from the Australian Academy of Science for the construction of the neutron monitor, and to record our appreciation of the excellent laboratory and computational facilities provided by Prof. H. Messel.

SEPARATION AND CHARACTERIZATION OF TWO COERULOPLASMINS FROM HUMAN SERUM

By Dr. LARS BROMAN

Institute of Biochemistry and Department of Psychiatry, University Hospital, University of Uppsala

THE serum constituent coeruloplasmin has recently been discussed as a factor possibly connected with mental diseases[1,2]. The application in this field of research of a well-known histochemical oxidase reagent, dimethyl-*p*-phenylene diamine, provides a convenient photometric method for estimating the enzymic activity of this protein[3] which contains copper. Oxidase measurements on serum have, however, little, if any, value as a diagnostic tool[4]. Many etiologically different diseases, and normal pregnancy, are characterized by increased levels of coeruloplasmin[5]. In some quarters this increment is assumed to be adaptive to an enhanced production of biologically active metabolites, the rapid destruction of which is essential for normal function. A precise knowledge of the physiological significance of coeruloplasmin is, however, still lacking.

With the exception of the work of Uriel *et al.*[6], no attempts have been made so far to separate the serum proteins and to compare their ability to oxidize dimethyl-*p*-phenylene diamine or related substances. This communication gives a brief description of a series of experiments based on the general assumption that the oxidation of dimethyl-*p*-phenylene diamine by whole serum is brought about by several more or less related enzymes, independently. Serum was fractionated with a calcium phosphate column and the existence of two chromatographically different oxidizing enzymes was demonstrated with the use of an improved technique, which excludes irrelevant influence from contaminating non-enzymic copper. Finally, it has been demonstrated that combinations of certain organic acids and chloride ions are powerful inhibitors of coeruloplasmin, a fact which has certain physiological implications.

The starting material used was serum from in-patients at a mental asylum. The subjects chosen were not undergoing heavy treatments at the time of sampling, such as insulin, chlorpromazine or electric shock.

The oxidase activity measurements were performed as follows. (This work was done independently of that of Humoller *et al.*[7], which was only recently brought to my notice.) Stock solution I was prepared by dissolving 3·120 gm. of dimethyl-*p*-phenylene diamine dihydrochloride (No. 3067, Merck, Darmstadt) and 3·72 gm. of the disodium salt of ethylenediamine tetraacetic acid (Hopkin and Williams Ltd., Chadwell Heath, Essex) in 50 ml. of 4 *N* hydrochloric acid and diluting with distilled water to 100 ml. Solution I was stored in plastic tubes at about −20° C. Stock solution II was a triethylamine–acetic acid buffer with *p*H 5·5 (0·50 *M* with respect to triethylamine, 0·58 *M* with respect to acetic acid). The substrate solution used was made up from 1 ml. of solution I and 50 ml. of solution II diluted with distilled water to a volume of 250 ml. The final *p*H was about 5·3 at 20°. Depending on the range of the oxidase concentration expected in the fractions, aliquots of 10–200 μl. were pipetted into suitable test-tubes and placed in an ice-bath. Using a semi-automatic syringe[8], 2 ml. of the cooled substrate solution was rapidly distributed into each test-tube. The whole set of tubes was then placed in a 37° C. thermostat for 10 min. and afterwards transferred to ice water, where it remained during the reading of the extinction at 552 mμ, using a 1·0 cm. cell and a Beckman *B* spectrophotometer. Usually 12 blanks without enzyme and 6 standard samples were included in each set.

The function of the ethylenediamine tetraacetic acid is to suppress the non-enzymic oxidation of the substrate which is mainly due to contaminating cupric ions. Copper forms a chelate with ethylenediamine tetraacetic acid in the molar ratio of 1 : 1, and at *p*H 3·5 or higher the chelation is almost complete[9].

Fig. 1 shows that the blank activity (open squares) is practically abolished by concentrations of ethylenediamine tetraacetic acid higher than about 10^{-6} *M*. This corresponds to the expected level of copper contamination in water and chemicals. That cupric ions do have a relatively intense oxidizing effect on dimethyl-*p*-phenylene diamine is demonstrated by the crossed-square curve, which was obtained with $4 \cdot 75 \times 10^{-5}$ *M* cupric chloride in the substrate. Ethylenediamine tetraacetic acid concentrations higher than the equivalent to this amount again suppress the catalytic activity. Thus, the cupric ethylenediamine tetraacetic acid chelate has no ability to oxidize dimethyl-*p*-phenylene diamine.

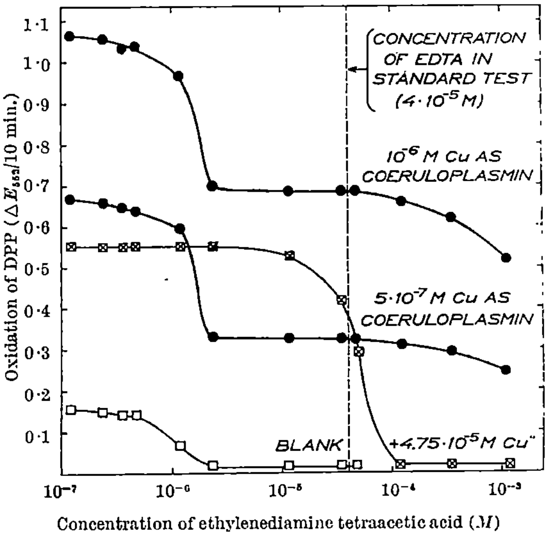

Fig. 1. Effect of different concentration of ethylenediamine tetraacetic acid on the oxidation of dimethyl-*p*-phenylene diamine. □—□, No additions; ×—×, $4 \cdot 75 \times 10^{-5}$ *M* cupric chloride; ●—●, with two different concentrations of coeruloplasmin

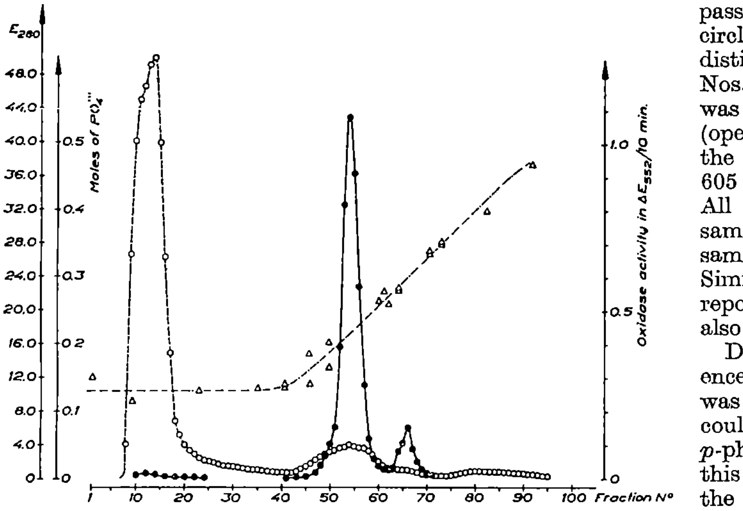

Fig. 2. Gradient elution chromatography of 9 ml. of serum on a column with 11·2 ml. of hydroxylapatite. Fraction volumes about 1·5 ml. ○—○, extinction at 280 mμ; ●—●, oxidase activity; △, phosphate concentration

Experiments with iron indicated that ethylenediamine tetraacetic acid had no influence whatever on the comparatively moderate oxidation of dimethyl-*p*-phenylene diamine brought about by added quantities of ferric chloride (cf., however, Green *et al.*[10]). The question remains open whether or not ethylenediamine tetraacetic acid is able to counteract a possibly increased catalytic activity of metal-protein complexes of non-enzymatic character, notably those with copper[11]. Fig. 1 demonstrates also that 4×10^{-5} *M* ethylenediamine tetraacetic acid has no inhibitory effect on the enzymatic oxidation of dimethyl-*p*-phenylene diamine by coeruloplasmin (black circles). This concentration of ethylenediamine tetraacetic acid was used in the standard test for the oxidase activity and is quite sufficient to suppress the catalytic blank oxidation commonly met with. Fig. 1 shows also that, during standard conditions, a doubling of the coeruloplasmin concentration will give rise to approximately twice the extinction at 552 mμ (black circles).

The chromatographic fractionation of the serum was carried out with a calcium phosphate (hydroxylapatite)[12] column, chiefly because of its high capacity for coeruloplasmin[13]. The column here used contained 11·2 ml. of hydroxylapatite (4·2 gm. dry weight) and the chromatogram was developed with a linear gradient of phosphate buffer, produced with an open mixing chamber and a conical depot flask[14]. At the start of the experiment, the column was in equilibrium with 0·125 *M* phosphate buffer and the mixing chamber contained 65 ml. of the same buffer, while the depot flask was filled with 250 ml. of 0·66 *M* phosphate buffer of the same *p*H, 6·8. With a hydrostatic pressure of about 130 cm. the flow rate was around 2 ml. per hr. Before the application to the column, the serum was dialysed against a 0·125 *M* potassium phosphate buffer of *p*H 6·8 for about 20 hr. Both dialysis and chromatography were carried out in a cold room at +4° C. Fig. 2 shows a typical result when 9 ml. of dialysed serum were chromatographed under these conditions. The readings of the extinction at 280 mμ for the different fractions (open circles) show that the bulk of the serum proteins are not adsorbed but appear as a large peak (fractions Nos. 9–16) immediately after the dead volume has passed. All the oxidase activity (black circles) was retained and appeared as two distinct zones (with maxima in fractions Nos. 54 and 66). The outcoming gradient was checked with phosphate determinations[15] (open triangles). Both the oxidases showed the same spectrum with maximum at 605 mμ, characteristic of coeruloplasmin[16]. All other sera investigated have shown the same oxidase heterogeneity and about the same proportion between the two peaks. Similar types of heterogeneity have been reported for many enzymes and recently also for another oxidase[17].

During attempts to find enzymic differences between these two coeruloplasmins, it was observed that certain organic acids could act as powerful inhibitors of dimethyl-*p*-phenylene diamine oxidation. Moreover, this inhibition seemed to be conditioned by the pretreatment of the coeruloplasmin. Fig. 3 illustrates the effect of varying concentrations of maleic (*A*), fumaric (*B*), salicylic (*C*), and oxalic acids (*D*) on the oxidase activity of a coeruloplasmin preparation, which had been dialysed for about 44 hr. against a 0·9 per cent sodium chloride solution. Phthalic acid caused an inhibition of the same order as did salicylic acid. If, however, the same amount of the identical coeruloplasmin was dialysed for 44 hr. against 0·125 *M* potassium phosphate buffer, *p*H 6·8, no significant inhibition could be demonstrated (curve A_1). Dialysis against 0·2 *M* sodium acetate buffer, *p*H 5·7, also prevented the inhibiting effect of maleic acid. In all these experiments the inhibitor was mixed with the coeruloplasmin about one hour before the determination of the activity, during which period it was stored at +4° C.

The effect of ions on the coeruloplasmin inhibition has several physiological implications; in particular, it appears that the control mechanism of the oxidase activity *in vivo* may be of a similar nature. It is hoped to treat this problem, as well as possible correlations with clinical data, during further investigations.

This work has been supported by Thånells Memorial Foundation for Research in Psychiatry and by the

PROTOPLASMIC STREAMING AND WALL STRUCTURE IN *NITELLA*

By M. C. PROBINE and PROF. R. D. PRESTON, F.R.S.

Botany Department, University of Leeds

DURING the course of work in progress on the cell wall structure of the alga *Nitella opaca* Ag., some observations have been made which may have a bearing on the mechanism of orientation of the cellulose component in the wall of this alga.

The internodes of *Nitella opaca* Ag. are large single cells, the mature cells of which may be several centimetres long. When the wall of a living *Nitella* cell is viewed with a hand lens, two colourless lines in an otherwise uniform green layer of stationary chloroplasts are visible. These lines are on opposite sides of the cylindrical wall and are so directed as to make a right-hand spiral around the wall. When viewed under a microscope at a higher magnification, it is obvious that the stationary chloroplasts are in regular files and that these files are approximately parallel to the two colourless striations. In the living cell, streaming of the protoplasm can be clearly seen, and it is apparent that the direction of streaming is the same as that in which the files of chloroplasts are arranged. On one side of the cell the protoplasm is streaming upwards, and on the other side it is streaming downwards, and the clear lines, revealed as narrow regions in which there are very few chloroplasts, are the boundaries between the ascending and descending streams.

The angle between the files of chloroplasts and the cell axis (which is a fairly accurate measure of the direction of protoplasmic streaming), has been measured for a number of internodal cells at various stages of growth, and it has been found that there is a correlation between the streaming angle of the protoplasm and the dimensions of the cell. In Fig. 1 the length/diameter ratio (l/d) is plotted against cot θ, where θ is the angle between the files of chloroplasts and longitudinal axis of the cell (so that θ is the streaming angle). The correlation between l/d and cot θ is highly significant. The correlation coefficient (R) is 0·91 (at the 0·001 level of significance, R = 0·617 for 23 degrees of freedom).

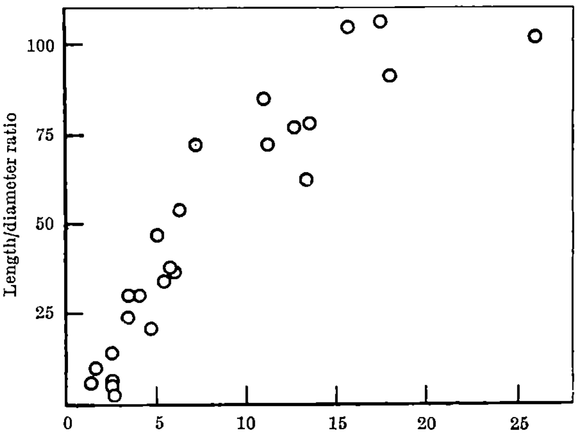

Fig. 1. Length/diameter ratio plotted against cot θ, where θ is the (streaming) angle between the files of chloroplasts and the longitudinal axis of the cell. Each point refers to a separate cell

The regression equation is of the form,

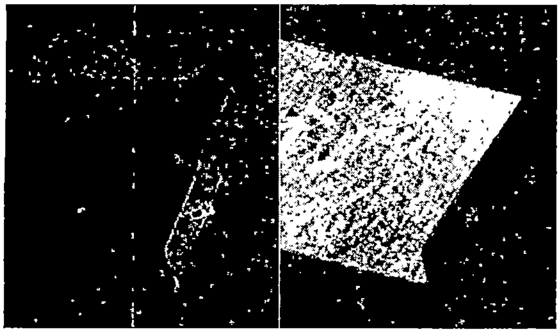
$$l/d = a + b \cot \theta$$

where θ is the streaming angle, l the length of cell, d the diameter of cell and a and b are constants. There is some evidence, however, that this linear relation is only an approximation, and that the actual relation is rather more complex.

Since the direction of protoplasmic streaming is so well defined, *Nitella* is an ideal material to examine for any correlation with cellulose chain direction in the cell wall. Since the streaming angle is a function of cell dimensions (and, therefore, of the age of the cell) it is possible to obtain cells with a wide range of streaming angles by selecting cells varying in age from the very young to the mature. The appropriate observations have therefore been made on a series of cells of various ages. The streaming angle was measured on the living cell. The major extinction position of a single cell wall with respect to the cell axis was measured with a polarizing microscope in the following way. The ends of the cell were cut off at an oblique angle to the cell axis, the protoplasm removed by stroking the cell gently under water, and the cell mounted on the slide in dilute glycerine. Because the cell was cut obliquely to the cell axis it was possible to mount it in such a way that when flattened by the cover-slip a fairly large area of single cell wall was visible at each end of the cell (Fig. 2).

It was found that the direction of the major extinction position followed a flat helix around the cylindrical wall, and that the helix angle varied with the age of the cell and, therefore, with the streaming angle and also with the dimensions of the cell. The results are shown graphically in Fig. 3. The correlation between streaming angle and angle of major extinction position is highly significant. The correlation coefficient (R) is 0·85 (at the 0·001 level of significance, $R = 0{\cdot}617$ for 23 degrees of freedom).

These latter results are in contradiction to those obtained by Green and Chapman[1] for *Nitella axillaris* Braun. They state that "Structural investigations reveal that the cellulose microfibrils of the wall are well oriented and run strictly in the transverse direction. This orientation is found in all portions of the wall and in all stages of its development". Unless there is a genuine difference between these two species there seems to be a conflict here. An apparent displacement of the major extinction position from its true position can of course arise through, for example, a misalignment of the cross-wires in the microscope. Fig. 2 is designed to show that no such error is a contributing factor in the present case and fully to document the helical arrangement of the major extinction position. In Fig. 2*a* the double wall (on the left) is extinguished while the single wall (on the right) is bright; in Fig. 2*b* the single wall is extinguished while the double wall is bright. A moment's thought will satisfy the reader that the major extinction position of the single wall must be tilted to the transverse. It seems that the wall of *Nitella axillaris* Braun should be re-examined in the light of these results. The matter is of some importance for two reasons. First, the observed correlation between streaming angle and major extinction position raises once again the question of the part played by streaming in the orientation of the anisotropic particles being incorporated in a new wall layer. It was observed many years ago by Denham[2] that the directions of protoplasmic streaming and of wall striations were often identical, and on this basis he suggested mechanisms whereby streaming might cause orientation in cell walls. Although this idea attracted considerable attention at the time and led to a good deal of speculation, the subsequent observation by Martens[3] that the striations concerned lay deep in the wall and not on the inner face, against the cytoplasm, led to an abandonment of the whole concept which was perhaps premature. The correlation observed here is not quite of the type suggested by Denham, since the streaming direction and the wall major extinction position tend to lie at right angles to each other. Moreover, since the chloroplasts are stationary, it does not seem likely that the cytoplasm near the wall is in movement. It could be, however, that the proteins of this surface layer are oriented by the streaming of those inner regions of the cytoplasm in which movement does occur and that these in turn are responsible for wall orientation. The present observations offer no evidence on this point. Secondly, it is possible that the phenomenon of spiral growth exhibited by these two species of alga might be more simply explained in terms of the type of spiral structure we have described for *Nitella opaca* Ag., than it could be if the major extinction position, as stated for *Nitella axillaris* Braun, is indeed strictly transverse; perhaps along the lines already suggested for the sporangiosphores of *Phycomyces*[4–6].



(*a*) (*b*)

Fig. 2. Cell wall of *Nitella opaca* Ag. photographed between crossed nicols (× 75). In Fig. 2*a* the double wall (on the left) is extinguished while the single wall (on the right) is bright. In Fig. 2*b*, after a rotation of the cell through 14 deg., the single wall is extinguished while the double wall is bright. The major extinction position of the wall is clearly not transverse

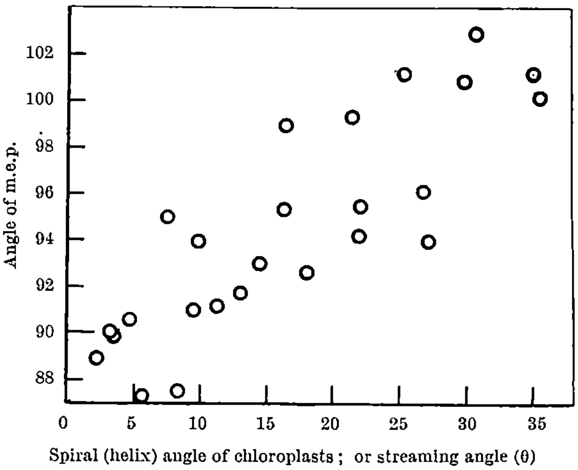


Fig. 3. Angle of major extinction position plotted against spiral helix angle of chloroplasts, or streaming angle θ. Angles are measured with respect to longitudinal axis of cell. For angles less than 90°, the major extinction position and the streaming angle are so directed as to make a right-hand spiral around the wall; for angles greater than 90° the spiral is in the left-hand sense

It has been shown that there are correlations both between cell dimensions and streaming angle and between streaming angle and the angle of the major extinction position of the cell wall. There will, therefore, also be a correlation between the angle of the major extinction position and cell dimensions. It is interesting to recall that a correlation between cell dimensions and the angle of the major extinction position has been shown to exist for some other types of plant cell, namely, conifer tracheids, bamboo fibres, and sisal fibres[7]. It does not, however, seem appropriate at this time to speculate as to whether these similar phenomena owe their existence to similar growth mechanisms.

We wish to acknowledge our indebtedness to a New Zealand National Research Fellowship grant to one of us (M. C. P.) which is enabling this work to be carried out.

Nuclear Magnetic Resonance Spectra from a Crystal rotated at High Speed

Hindered molecular rotation in solids reduces the width of their observed nuclear magnetic resonance spectra, with a consequent decrease in the measured second moments[1]. By contrast, on general theoretical grounds it has been shown[2] that the second moments of dipolar-broadened spectra should remain invariant and should not be reduced by such motion. In a recent explanation[3] of this apparent discrepancy the nuclear magnetic interaction was divided into two parts, namely, a steady mean interaction and a fluctuating part. The steady mean interaction is less than the interaction in a static crystal devoid of hindered rotation and generates an observed spectrum narrower than that of the static crystal. The fluctuating part of the interaction generates side-spectra set at integral multiples of the frequency of molecular rotation on either side of the central narrowed spectrum. Since the molecules do not rotate uniformly, but are re-oriented with an irregular motion, these side-spectra are dispersed over a band of frequencies with an intensity too weak to be observed. It was shown, however[3], that when these weak side-spectra are included the second moment does indeed remain invariant even though the second moment of the central portion, which is all that is observed experimentally, becomes smaller.

Since this explanation requires the existence of side-spectra which are too weak in intensity normally to be seen, it seemed desirable to devise an experiment which would render them observable. If all the molecules in a solid were to rotate with the same uniform frequency, the side-spectra would then be centred at well-defined frequencies and should, under suitable conditions, have sufficient intensity to be observed. The most convenient way in which to achieve this situation is to take a crystal within which there is no appreciable motion of the nuclei and to rotate it uniformly. In this way all nuclei in the crystal rotate with the same uniform frequency with respect to their neighbours. Since the accepted criterion[1] for spectral narrowing is a rotation-rate at least comparable with the width of the spectrum, it was clear that a high speed of rotation would be necessary.

Using an air-driven rotor, a single crystal of sodium chloride was spun at speeds up to 50,000 revolutions per minute about the [001] direction in a magnetic field of 6,000 gauss directed normally to the axis of rotation. With this geometry it may readily be shown[3] that side-spectra should occur only at even multiples of the rotation frequency ν_r on either side of the narrowed central spectrum. Examples of the sodium-23 resonance derivative spectra recorded with a modified Pound–Watkins spectrometer are shown in Fig. 1. The first-order side-spectra are clearly seen at the highest rotation-rates and occur, as predicted, at a separation of $2\nu_r$ from the centre of the spectrum. The central portion is approximately halved in width as the theory requires for this case. There is good general agreement between the shape of the derivatives recorded and those calculated, at all rates of rotation. In particular, at the highest rate of rotation (800 c./s.), where the first side-spectra are well resolved, their intensity relative to that of the central portion is in satisfactory agreement with theory. At 800 c./s. the expected relative intensity of the second side-spectra at $\pm 4\nu_r$ is less than 1 per cent, and they have not been observed.

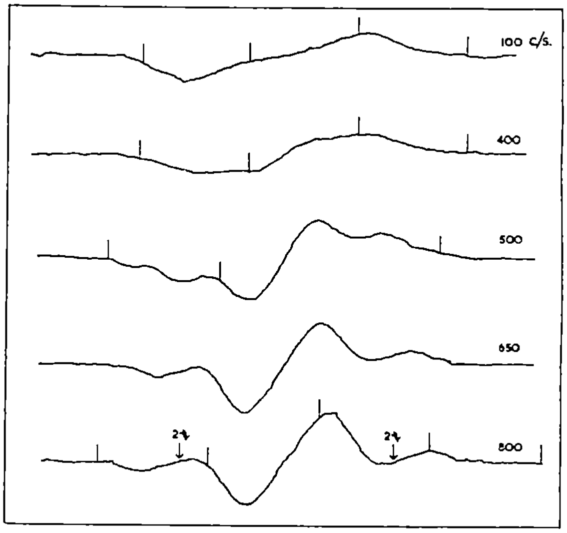

Fig. 1. Sodium-23 nuclear magnetic resonance derivative spectra of a single crystal of sodium chloride rotated at the rates indicated. The markers on the recordings are 1,660 c./s. apart

The second moments of spectra recorded at different rotation-rates are given in Table 1; the rotation-rates were measured photoelectrically.

Table 1

ν_r (c./s.)	Second moment (gauss^2)	ν_r (c./s.)	Second moment (gauss^2)
100	0·57	500	0·55
200	0·54	700	0·56
400	0·57	800	0·59

The mean theoretical value of the second moment for the static crystal with the magnetic field in the (001) plane has been found from Van Vleck's formula[4] to be 0·55 gauss^2. This value is in satisfactory agreement with the results in Table 1 and verifies the invariance of the second moment.

This experiment shows in a direct manner that the relative rotation of nuclei in solids does cause a narrowing of the nuclear magnetic resonance spectrum. Moreover, in addition to demonstrating the presence of side-spectra and verifying the invariance of the second moment within the limits of the experimental uncertainty, the experiment also shows directly that for spectral narrowing the necessary rate of nuclear motion is of the order of the spectral width. (The r.m.s. line-width 0·74 gauss is equivalent to 833 c./s.)

Transmission Electron Microscopy of Beryllium

We have prepared thin films of beryllium in which it is possible to observe directly the arrangements of dislocations and other structural defects by transmission electron microscopy. The films were made by two methods.

Beryllium was deposited as thin (0·03–0·05 mm.) polycrystalline flake on cool surfaces from metal melted by electron bombardment. This flake was etched in a dilute aqueous solution of hydrofluoric and nitric acids to give specimens suitable for examination. The grain-size was about 1μ. Single-crystal specimens were prepared by cleaving a beryllium crystal parallel to the basal plane to obtain a flake which was ground and polished down to a thickness of 0·02 mm. and then etched. Specimens were examined using 70-kV. electrons in the prototype Metropolitan-Vickers *E.M.*6 electron microscope.

Grain boundaries and single perfect dislocations were clearly visible in the evaporated flake. Many grains were structurally perfect while others contained several dislocations. From the electron-optical fringes on the grain boundaries the films were shown to be several thousand angstrom units thick.

A low-magnification electron micrograph of a single-crystal thin film is shown in Fig. 1. The long, sharp, roughly parallel lines make a $[1\bar{1}00]$ trace on the basal plane. From this and the fact that they make a line-projection on (0001), it may be concluded that they are either due to single dislocation lines or to $[11\bar{2}0]$ planes. As the difference in contrast on either side of them is often quite marked (it is similar to that on crossing a well-formed sub-boundary in aluminium[1,2] or germanium[3]) there must be a considerable misorientation associated with them. Furthermore, the contrast on them is higher than that usually associated with single dislocations ; they are therefore planes of a $(11\bar{2}0)$-type. X-ray and conventional metallographic techniques have revealed the existence of $\{11\bar{2}0\}$ planes which are effectively tilt boundaries, and which are believed to be important in the fracture mechanisms observed in beryllium[4]. At points such as *A* in Fig. 1, a boundary with a $[1\bar{1}00]$ trace is observed to end in a fan-like array of dislocations. This can be understood if this boundary consisted of dislocations parallel to the basal plane. Coupling the X-ray and metallographic evidence with the present observations one may conclude that the boundaries consist of edge dislocations stacked normal to the basal plane. It is yet to be determined whether these boundaries ('bend planes') are formed during the growth of the crystal from the melt or during cleavage.

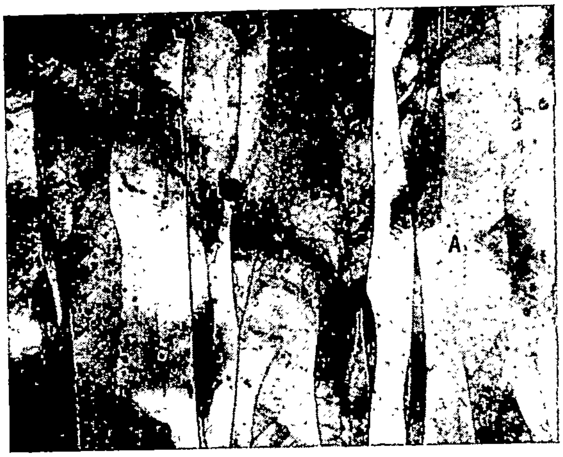

Fig. 1. Bend planes and dislocations in beryllium. At *A* the constituent dislocations of a bend plane fan out into an array. (× 4,000)

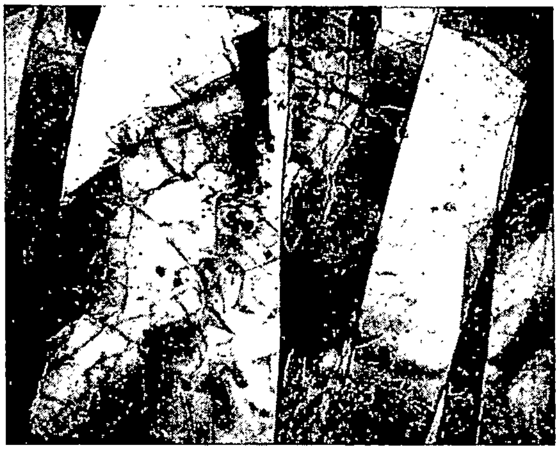

Fig. 2. Bend planes, dislocations and dislocation loops in beryllium. (×40,000)

Between the sharp parallel lines in Fig. 1 there are randomly oriented lines believed, on the basis of similar studies of other materials, to be perfect dislocations more or less in the plane of the specimen. Fig. 2 shows bend planes and single dislocations at a higher magnification. Closed loops of dislocation line also occur ; these are probably due to the condensation of vacancies during solidification. The same mechanism probably accounts for the highly kinked nature of some of the dislocations.

The dislocation density in the single crystal was about 10^8/cm.^{2} : most of these dislocations were probably 'grown in'.

Dispersion of the Stress Optical Coefficient of the Alkali Halides

In recent years the dispersion of the stress optical coefficients of diamond[1], the alkali halides[2] and magnesium oxide[3] has been determined in the visible range of wave-lengths. The dispersion in fused quartz[4,5] has also been investigated from 5700 to 2500 A. The observed dispersion is of the order of a few per cent for all these materials. In the present investigation the dispersion of the stress optical coefficient $C = n^3(q_{11} - q_{12})/2$ has been determined from the visible range to 2400 A. The method of measurement combines the differential feature of Bansigir and Iyengar's[2] method with the photo-

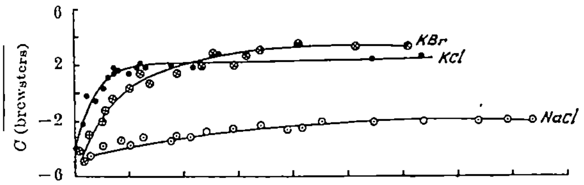

Fig. 1. Dispersion of the stress optical coefficient $C = n^3(q_{11}-q_{12})/2$ of three alkali halides

graphic method of Jog[6]. Using fused quartz (presented by the Thermal Syndicate to Prof. R. S. Krishnan) as the standard, the stress optical coefficient of the alkali halides is obtained by determining the position of the dark bands in the spectrum of light polarized at 45° to the direction of stress and passed through the fused quartz specimen loaded suitably, the stressed alkali halide crystal and an analyser in the crossed position. The position of the dark bands is determined by the equation:

$$C_1W_1/t_1 + CW/t = n\lambda$$

where C is the stress optical coefficient of the material for wave-length λ; W is the load applied on it; t is its thickness and n is the order of the band. C_1, W_1 and t_1 refer to the standard and C, W and t to the alkali halide used.

In Fig. 1 are given the curves depicting C as a function of wave-length. As the method is differential, the accuracy in determining C is not very high. For sodium chloride, the mean square deviation of the experimental points from the curve is 0·16 brewsters while for potassium chloride and bromide it is 0·3 brewster. In Table 1 the values of $(q_{11}-q_{12})$ at 4800 A. determined in the present investigation are compared with the values in the literature.

Table 1. $(q_{11} - q_{12}) = 2C/n^3$ FOR THE ALKALI HALIDES (VALUES IN BREWSTERS)

Substance	Present value	Value in lit.	Reference
Sodium chloride	− 1·12	− 1·17 − 1·18	2 7
Potassium chloride	1·42	1·47 1·85 1·37	2 8 7
Potassium bromide	1·76	1·76 1·70 1·58	2 7 9

From the curves we see that: (1) in the visible region the dispersion is only a few per cent in agreement with the observations of Bansigir and Iyengar; (2) as one approaches the ultra-violet, the dispersion becomes enormous; for example, in sodium chloride C varies from −1·9 at 5800 A. to −4·5 brewsters at 2500 A., in potassium chloride from +2·4 at 5000 A. to −2·0 brewsters at 2450 A. and in potassium bromide from +3·4 at 4800 A. to −4·6 brewsters at 2450 A.; (3) the curves for potassium chloride and bromide show that the stress optical coefficient for these crystals changes sign at 2550 A. and 2760 A. respectively. It therefore appears that these crystals which belong to Mueller's[10] class IV ($q_{11} - q_{12}$ +ive; q_{44} −ive) go over to Mueller's class II ($q_{11} - q_{12}$ −ive; q_{44} −ive Ex. sodium chloride) as one moves into the ultra-violet.

Further work is in progress, and the results will be published later.

My thanks are due to Prof. R. S. Krishnan for his interest, to the Thermal Syndicate, Ltd., England, for the gift of the fused quartz specimen and to the National Institute of Sciences of India for a research fellowship.

Thermal Contact at Low Temperatures

MECHANICAL heat switches are becoming of increasing importance in low-temperature calorimetry, and in order to study thermal contact both for this practical application and from interest in the mechanism of heat transfer, we have built the apparatus sketched in Fig. 1. This differs from the apparatus described by Berman[1] mainly in the method of applying the load by a screw, and measuring it by strain gauges cemented to the cantilever.

Our first experiments were on copper, and two typical load cycles are shown in Fig. 2. At 18° K. the conductance, Q (the heat flow per unit temperature difference across the junction), is proportional to $\sqrt{W}$, where W is the load. At 4° K. the power of W is slightly higher, and the absolute values and the dependence on load agree very closely with Berman's results. The dependence on temperature of the conductance, shown in Fig. 3, is smaller than was found by Berman.

From experiments on electrical contact[2], it has been found that the radius of the microjunctions,

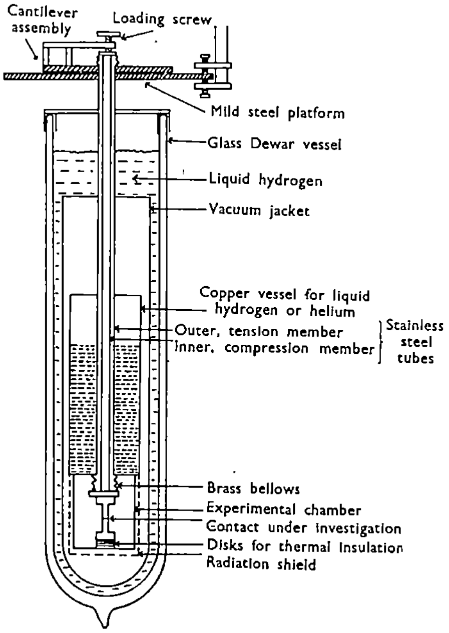

Fig. 1. Schematic diagram of contact apparatus

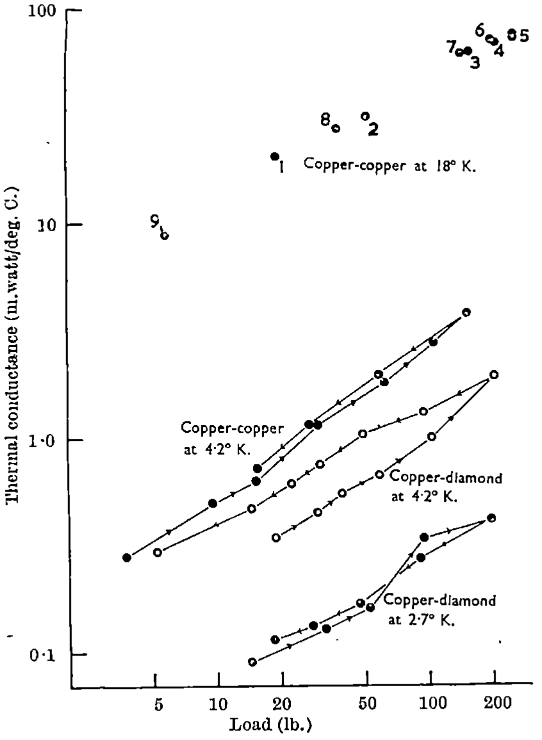

Fig. 2. Variation of thermal conductance with load after contact had been broken at the working temperature. (Numbers or arrows indicate the order in which measurements were made)

where true contact between metals occurs, is of the order of 10^{-2} cm. Even at 4° K., both the electron and phonon mean free paths in copper are not more than 10^{-3} cm., so that the theory of a spreading resistance[3] should apply. A junction of radius r in a material of bulk thermal conductivity κ presents a thermal resistance $1/2r\kappa$, so that, for n junctions in parallel:

$$Q = 2nr\kappa$$

The total area of real contact, A, is determined by the yield pressure of the material, P. For plastic deformation of the asperities, as would occur for an increasing load:

$$A = n\pi r^2 = W/P$$

whence:

$$Q = 2\kappa(nW/\pi P)^{1/2}$$

Tabor has shown that for steel, n varies roughly as $\sqrt{W}$, so that for increasing load Q should vary roughly as $W^{3/4}$ in reasonable agreement with our results. If the asperities deform elastically on reducing the load, $A \propto W^{2/3}$ and Q should vary as $W^{0\cdot 6}$. For the load cycles on copper there is, however, no significant difference between the two parts of the cycle.

If we modify Tabor's results on steel to take into account the lower yield pressure of copper, we would expect that for a load of 100 lb. applied at room temperature, $n \sim 20$ and $r \sim 10^{-2}$ cm. From the observed value of Q, κ at 4° K. would be 2×10^{-2} watts/cm. deg., which is remarkably close to the lattice conductivity of copper at this temperature.

The measured electrical conductance is of the order of 100 times smaller than corresponds to the heat conductance, suggesting that the microjunctions are between oxide layers on the asperities of the surfaces, with pure copper only in contact over a small fraction of the area. The oxide layer is, however, very thin compared with the size of the microjunctions, so that the electronic conductivity should be effective over the greater part of the constriction. As, in addition, the lattice heat conductivity varies as T^2, while the conductance measured in these experiments varies as $T^{1\cdot 3}$, the similarity between the derived value of κ at 4° K. and the lattice conductivity must be regarded as fortuitous.

There is evidence[4] that any non-metallic film on gold is broken at very small loads, and the whole contact is then electrically conducting. We have, therefore, measured the conductance of a gold contact, and the results at a load of 100 lb. are shown in Fig. 3. The electrical conductance was too high to be measured with our existing arrangement, but the thermal conductance was equivalent to less than 10 times our limit of measurement of electrical conductance.

As a gold–gold contact at helium temperatures is 25 times better than a copper–copper contact, we intend to examine the effect of gold-plating the copper rods, to avoid the oxide layer.

In a non-metallic crystal at low temperatures, the phonon mean free path can be several millimetres, and is thus much greater than the size of the surface asperities. We would, therefore, expect the junctions to act as apertures for radiation-like heat flow (this treatment of heat flow in crystals when the mean free

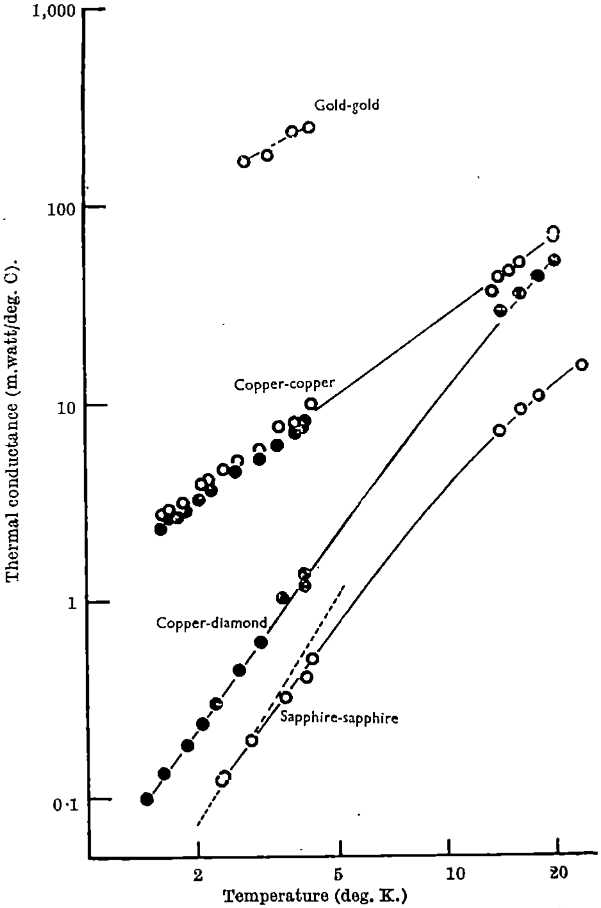

Fig. 3. The variation of thermal conductance with temperature at a load of 95 ± 5 lb., applied at room temperature. The measurements on the copper–copper contact at helium temperatures were made on two different days. ----, $Q = 9 \times 10^{-6}T^3$ watts/deg. C.

path is long has been used by Casimir[5]) and for apertures of zero thickness, $Q = \frac{1}{4}C_v/vA$, where C_v is the specific heat per unit volume and v is the mean phonon velocity. We have measured the contact between two artificial sapphire crystals, and the results for a load of 100 lb. are shown in Fig. 3. Using the hardness to determine A for this load applied at room temperature, the above equation gives $Q = 11 \times 10^{-6}T^3$ watts/deg. C. From 'talysurf' examination, the asperities are seen to have a height equal to about one-quarter of their diameter, and this would reduce the conductance by about 20 per cent. We therefore expect to find $Q \sim 9 \times 10^{-6}T^3$ watts/deg. C. This calculated curve is shown in Fig. 3 and can be seen to agree quite well with the experimental results, both in absolute magnitude and in the temperature variation. At the lowest temperatures, the experimental curve should probably be lowered by about 10 per cent because of heat leaks, which are significant at these low values of conductance. We have not made this correction as its value is uncertain, but it would certainly increase the slope of the experimental line.

Finally, we may mention that we were interested by the fact that the heat capacity of diamonds has been measured at low temperatures in a copper calorimeter without exchange gas[6]. We measured the thermal contact between two copper rods separated by a small diamond, and found that the conductance lies between that for two pieces of copper and the conductance between two rods of a hard substance like sapphire. The values shown in Figs. 2 and 3 are double the measured conductances and represent a single copper–diamond contact. The short equilibrium time in the heat capacity experiments must, therefore, be entirely due to the high thermal diffusivity of diamond at low temperatures, and is not related to any unusual properties of a diamond–copper contact.

Effect of the Carrier Gas on the Sensitivity of a Thermal Conductivity Detector in Gas Chromatography

IT appears to be a popular belief that the use of hydrogen or helium as the carrier gas in gas chromatography gives the highest sensitivity with a thermal conductivity detector, because the difference in thermal conductivity between organic vapours and hydrogen or helium is greater than for any other carrier gas[1,2]. This is not necessarily true, however, for the difference in temperature between the hot wire (at t_1° C.) and the body of the thermal conductivity cell (at t_0° C.) is inversely proportional to the thermal conductivity K_1 of the carrier gas :

$$t_1 - t_0 = a/K_1, \text{ where } a \text{ is constant.}$$

If the concentration of organic vapour in the carrier gas is x, the sensitivity of the detector is proportional to :

$$\frac{dt}{dx} = -\frac{a}{K_1^2}\cdot\frac{dK}{dx}$$

When x is small, dK/dx is approximately equal to $K_1 - K_2$, where K_2 is the thermal conductivity of the organic vapour.

$$\text{Hence } \frac{dt}{dx} = -\frac{a(K_1 - K_2)}{K_1^2}, \text{ approximately.}$$

Thus the sensitivity of the detector is inversely proportional to the square of the thermal conductivity of the carrier gas, and directly proportional to the difference in thermal conductivity. It follows that the carrier gas with the lowest thermal conductivity will give the highest sensitivity ; this has been confirmed experimentally by comparing the peak heights obtained from the same size of sample with helium and with argon carriers. The apparatus was a Griffin and George Mk. IIA V.P.C. apparatus, the sample was a mixture of equal parts of methane, ethane, and propane, and amounts ranging from 0·01 to 0·1 ml. were injected ; the relative sensitivities in terms of peak height (in.) per ml. of each gas were calculated from the average of six determinations with each carrier gas and the results were as shown in Table 1.

Table 1. RELATIVE SENSITIVITIES, AS PEAK HEIGHT (IN.) PER ML. OF HYDROCARBON GAS

Hydrocarbon	Helium carrier	Argon carrier
Methane	116	311
Ethane	98	190
Propane	25	28

Of the commoner inorganic gases, carbon dioxide (thermal conductivity $1 \cdot 37 \times 10^3$ ergs per cm. per sec. per deg. C.)[3], nitrous oxide ($1 \cdot 44 \times 10^3$) and argon ($1 \cdot 58 \times 10^3$) are likely to give the best results with thermal conductivity detectors in gas chromatography ; sulphur dioxide ($0 \cdot 77 \times 10^3$) and hydrogen sulphide ($1 \cdot 20 \times 10^3$) are probably too reactive to use as carrier gases except in special circumstances.

A Detector for Use with Capillary Tube Columns in Gas Chromatography

A RECENT development in gas chromatography is the use of columns made from metal capillary tubing, the inner surface of which is coated with a thin layer of stationary phase[1]. These columns promise greatly enhanced performance and resolution in the separation of volatile substances compared with the conventional packed-powder columns ; for optimum performance, however, capillary tube columns require small-bore tubing, a thin layer of stationary phase and a slow rate of gas flow, approximately 1 ml./min The small dimensions of these columns necessitate small loads in the region of 1 μgm. of the mixture to be separated, otherwise the stationary phase would bear excessive concentrations of the various components and the resolution of the column would suffer. The slow rate of gas flow combined with the outstanding resolving power of the columns causes the emergence of the more volatile components in a gas volume of only a few μl. These two properties of the capillary tube columns impose severe restrictions on the type of detector suitable for observing the emergence of vapour from the column. The smallness of the load demands high sensitivity, and the smallness of the retention volume demands a detector with a sensing volume at least as small. A detector was reported in which the concentration of vapour molecules emerging from the column was measured in terms of their ionization following collisions with metastable rare-gas atoms[2]. This detector is more than sufficiently sensitive for use with the capillary columns; it is, however, much too large (1–10 ml.) and cannot simply be scaled down in size to accommodate the requirements of the capillary columns. This communication describes a modified version of the detector with a sensing volume in the region of 1 μl.

The large-volume detector previously described consisted of an ionization chamber containing a source of ionizing radiation sufficient to provide a saturation current, usually in argon, of 10^{-8} amp. The carrier gas was led directly from the column into the ionization chamber. The electrons set free in the gas by the radiation were accelerated by the potential imposed on the chamber to velocities sufficient to excite a proportion of the argon atoms to their metastable state; the ionizing collisions between these excited atoms and the vapour molecules as they emerge from the column were observed as an increase in ionization current. The relatively large volume of this detector was determined principally by the fact that the primary ionization current was the product of the gas volume and the radiation intensity; very small volumes would require excessive radiation intensities. If, however, in this detector the anode is made small compared with the dimensions of the chamber the greater part of the electric field will reside close to the anode surface; thus the only region of the detector in which the primary electrons will be sufficiently accelerated to excite the argon atoms will be that in the immediate vicinity of the anode. This small volume then constitutes the sensing volume of the detector.

Fig. 1 illustrates a practical device based on this notion. It consists of an ionization chamber of similar dimensions to that previously described with the earlier detector, for example, 1 cm. diameter by 1 cm. deep. Gas from the column is led into the chamber along a narrow metal capillary tube which could be the end of the column itself. Within the chamber the capillary tube is enclosed in a sleeve of insulating material, polytetrafluoroethylene, the end of this sleeve being widened to form a small cylindrical chamber 1 mm. in diameter by 1 mm. deep. One end of this small chamber is open to the main chamber, and the metal capillary tube terminates at the base. The anode consists of a small bead fused on to the end of a short length of gold wire; the wire is inserted into the bore of the capillary tube until the bead is enclosed by the small chamber. The capillary tube, of course, serves as the electrical connexion to the anode. When a sealed source of ionizing radiation, for example, 10 mc. of strontium-90 or 80 μc. of radium *D*, is inserted in the main chamber and a potential of between 500 and 1,000 V. applied between the anode and cathode, the argon carrier gas is excited to its metastable state almost entirely within the confines of the small sensing chamber. To prevent slow changes in response caused by the reaction of vapour molecules with the smaller concentration of excited atoms in the outer chamber a scavenging flow of argon at, say, 50 ml./min. is passed through the outer chamber. Alternatively, a lesser scavenging flow or some other gas, say, dry air or nitrogen, may be used. These gases are both able to discharge the metastable argon atoms without producing ions and so limit the response to the small chamber where argon and vapour alone are present; they do nevertheless serve as efficient sources of primary electrons when irradiated by the sealed source.

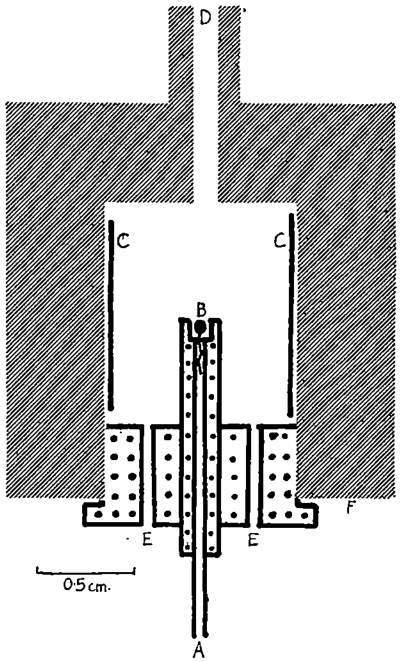

Fig. 1. The small-volume detector; details of construction: (*A*), inlet for gas from the chromatograph column; (*B*), anode; (*C*), source of ionizing radiation; (*D*) and (*E*), inlet and outlet for the scavenging gas; (*F*), cathode. Shaded, brass; stippled, polytetrafluoroethylene

The detector here described has been tested with a metal capillary column 125 ft. long, 0·01 in. in diameter and with a thin layer of squalane as the stationary phase. An efficiency of 30,000 theoretical plates was observed in the separation of a mixture of hydrocarbon vapours using a load of 0·3 μgm. The response of the detector is closely similar to that reported for the large-volume device both in terms of sensitivity and response to different substances. It is insensitive to small changes in temperature and pressure, but rather more sensitive to rate of gas flow. The response is linear with vapour concentration provided a series resistance of between 1 and 5×10^9 ohms is included in the source of applied potential.

I am indebted to Mr. D. H. Desty of British Petroleum, Ltd., for the loan of the capillary column and for his help and advice in its use.

Formation of Higher Bromo-Complexes of Tervalent Gold in Non-Aqueous Solution

TERVALENT gold is usually four-covalent in its compounds and possesses a square-planar arrangement associated with $5d6s6p^2$ bonding[1]. Complexes of gold(III) with a co-ordination number greater than four have recently been prepared by Harris and Nyholm[2]. These compounds are of the types $[Au(diarsine)_2X](ClO_4)_2$ and $[Au(diarsine)_2X_2]ClO_4$ (where X = Br or I and diarsine = *o*-phenylene*bis*-(dimethylarsine)). Bivalent palladium and platinum, which possess a similar d^8 electronic configuration, also exhibit co-ordination numbers greater than four with this ligand[3,4].

Harris, Livingstone and Reece[5] have recently reported the formation of the hexabromo-palladate(II) ion in nitrobenzene solution. The reaction of bromide ions with the tetrabromoaurate(III) ion has now been examined in non-aqueous solution. The $[AuBr_4]^-$ ion resembles the $[PdBr_4]^{2-}$ ion in that its absorption in nitrobenzene solution in the visible region is lowered by the addition of bromide ions. A continuous variation study (Fig. 1) in this solvent, using a differential spectrophotometric method[5], gives a maximum optical density depression near a ratio of two bromide ions to one $[AuBr_4]^-$ ion. This suggests the formation of the $[AuBr_6]^{3-}$ ion in this solution.

Measurements were also made on this system in nitromethane solution (Fig. 2). The use of this solvent enabled the absorption spectrum to be measured at shorter wave-lengths and the effect of much higher bromide concentrations to be studied. The $[AuBr_4]^-$ ion possesses a very broad absorption maximum in nitromethane ($\lambda_{\max.} = 394$ mμ; ε = 4,850). At high bromide concentrations, the intense red-brown colour of dilute solutions of this ion is discharged with the formation of a very pale yellow solution of the $[AuBr_6]^{3-}$ ion ($\lambda_{\max.} = 379$ mμ; ε = 550). It is possible that species such as $[AuBr_5]^{2-}$ and $[Au_2Br_{10}]^{4-}$ are also formed in this reaction, and this is being further investigated. In this connexion it is interesting to note that Bjerrum and Kirschner[6] have shown that $[Au(SCN)_5]^{2-}$ and $[Au(SCN)_6]^{3-}$ ions are formed in concentrated aqueous thiocyanate solutions containing tervalent gold.

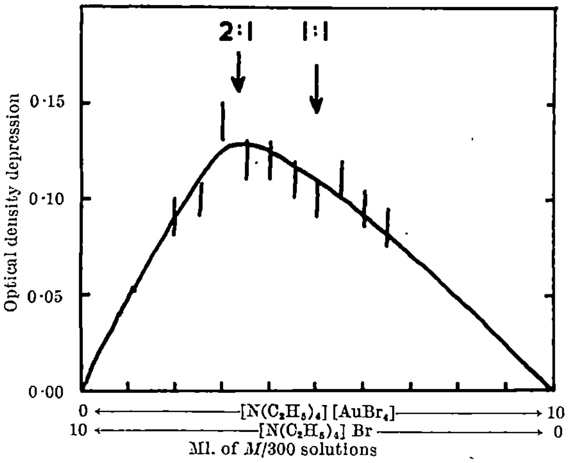

Fig. 1. Continuous variation study on nitrobenzene solutions of tetraethyl ammonium tetrabromoaurate(III) and bromide ions at 430 mμ in 0·50-cm. cells at 12° C. The theoretical end-points are shown

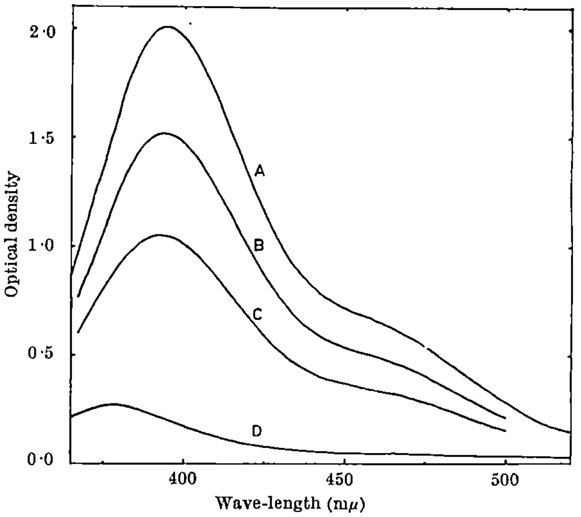

Fig. 2. Absorption spectrum of the tetrabromoaurate(III) ion in nitromethane solutions containing various concentrations of tetraethylammonium bromide. Cell size, 0·50 cm. *A*, *M*/1,200 tetraethylammonium tetrabromoaurate(III); *B*, solution *A* plus 0·1 *M* bromide; *C*, solution *A* plus 0·25 *M* bromide; *D*, solution *A* containing 0·5–0·7 *M* bromide, corrected for absorption by tetraethylammonium bromide

The formation of six-covalent gold(III) complexes such as $[Au(diarsine)_2X_2]ClO_4$ has been attributed to the use by the gold atom of two additional elongated $6p6d$ bonds normal to its usual $5d6s6p^2$ square-planar arrangement[3]. Six-covalent species such as the $[AuBr_6]^{3-}$ ion would be expected to possess a distorted octahedral structure due to the repulsion effect of the filled $5d_z{}^2$ non-bonding gold orbital which points along the axis of the two additional Au—Br bonds. Such a distorted octahedral arrangement for gold(III) has been observed by Elliot and Pauling[7] in the structure of the compound $Cs_2[Au^{III}Cl_4][Au^{I}Cl_2]$. Here, each gold(III) atom is surrounded by four chlorine atoms at 2·42 A. with two further chlorine atoms (from $[AuCl_2]^-$ ions) at 3·1 A.

Use of Iron-52 as a Radioactive Tracer

Two radioactive isotopes of iron, namely, iron-59 (half-life 45 days) and iron-55 (half-life 3 years), have been used extensively for tracer investigations in medical and biological studies. We should like to direct attention to another isotope of iron, iron-52, the physical characteristics of which may be of advantage in some investigations.

The half-life of iron-52 is quoted in the literature as 7·8 hr. [1] and 8·3 hr. [2], and our measurements give a figure of 8·4 ± 0·1 hr. The isotope decays by K-capture or by positron emission, the maximum energy of the positrons being 0·8 MeV[3]. The branching ratio is 60 per cent electron capture to 40 per cent positron emission[4]. All disintegrations give rise to a gamma-ray of 170 keV. (Coleman, C. F., private communication, 1958). The great majority of them result in the formation of manganese-52 (isomeric state), which decays with a half-life of 21 min. directly to chromium-52, giving a gamma-ray of 1·46 MeV.[5]. The maximum energy of the positrons produced in this latter process is 2·6 MeV. A small proportion of the events (not more than 5 per cent) produce manganese-52 in the ground-state which decays to chromium-52, with a half-life of 6 days, so that the activity of the ground-state manganese-52 produced is very small, and its presence may be ignored or a minor correction applied.

Iron-52 has been prepared in the Medical Research Council cyclotron at Hammersmith Hospital, by bombarding natural chromium with 30 MeV. alpha-particles, the reaction being chromium-50 (α, 2n) iron-52. Samples of the resulting iron-52 have been separated chemically, initially by Dr. P. Reasbeck and afterwards by one of us, giving specimens of high specific activity. However, during the bombardment the isotope iron-55 is also produced, by the reactions chromium-53 (α, 2n) iron-55 and chromium-52 (α, n) iron-55, the relative amount formed depending on the α-particle energy and the target thickness used. Since, however, iron-55 produces no radiation other than a K-capture X-ray of 6 keV., it is possible to measure the radioactivity in counting systems insensitive to this isotope. Its presence does, however, increase the radiation dose delivered to the subject, and must be remembered when human applications are being considered.

It is necessary to consider how far the suitability of iron-52 for biological tracer investigations is affected by the unstable nature of its daughter product. In many experiments this will be of little consequence. This is so when the material which is being measured can be isolated from active metabolic changes, as in the case of plasma samples in blood-clearance studies. Here, provided the specimen is left for an hour, to ensure that the manganese-52 (isomeric state) is in equilibrium with the iron, the activity of the sample depends solely on the iron metabolism of the system from which it was obtained. Measurements of plasma clearance, using iron-52, in various animals have shown the expected exponential patterns. In one animal, a dog, the test was repeated a few days later, using iron-59, when a very similar result for the time of half-disappearance was obtained.

However, if measurements are to be made while metabolic changes are occurring, as, for example, in the case of *in vivo* surface counting, the possibility arises that a different metabolism and distribution of the daughter isotope will confuse the iron studies. There is as yet little information available on the fate of atoms formed in tissue as a result of radioactive decay. When using iron-52 it is clearly very important to know if the manganese-52 (isomeric state) remains at the site of its formation for a time long compared with its half-life, so that the observed distribution of radioactivity will be characteristic of the distribution of the iron. We have made a limited investigation of this problem by injecting some iron-52 intravenously into several rats. Some six hours later the rats were killed and various organs (liver, spleen, kidney, femur, etc.) rapidly resected. The activity in the organs was then followed to see if there was any change occurring with a half-period of 20 min., such as would occur if the daughter product were out of equilibrium with its parent. No such change of activity was observed in any of the specimens studied. It seems probable, therefore, that in these animals the major part of the manganese-52 (isomeric state) decayed at the sites of its formation. If the same is true in man it will then be possible to use iron-52 for *in vivo* studies.

The fact that iron-52 is a positron emitter may be of use when accurate location of the activity is desired because coincidence-counting techniques on the annihilation radiation would be possible. It may thus be possible to give sufficient of the isotope to enable studies to be made of the distribution and volume of erythropoietic tissue, a point of great importance, for example, for the dosimetry of phosphorus-32 therapy in polycythæmia and other hæmatological conditions.

The advantages of iron-52 derive principally from its short half-life. This implies that in tests for which the isotope is suitable a smaller integral radiation dose may be given to the patient. Unfortunately the integral radiation dose given when iron-52 is used is increased by the presence of the iron-55. Initial measurements indicate that the level of iron-55 activity is unlikely to exceed 50 per cent of that of the iron-52 obtained, and it may be possible to reduce this by modifications in the production techniques. The specific γ-ray emission of iron-52 and manganese-52 (isomeric state) in equilibrium is 16, and we consider that a dose of 3 μc. of iron-52 is sufficient for plasma clearance studies if the samples are counted in a well-type scintillation counter. This would result in a maximum radiation dose to the blood of the patient of about 15 mr. from the iron-52, and, assuming a 600-days effective half-life, of approximately 200 mr. from the iron-55. This compares with approximately 300 mr. from 3 μc. of iron-59, though because of its lower specific γ-ray emission more than this quantity would be required to give similar counting accuracy.

The principal value of iron-52 appears to lie in the fact that it enables studies of plasma iron turnover and early surface counting to be repeated at short intervals. It must be remembered, however, that studies of iron absorption and of red cell utilization are not possible with this isotope as they require a period of days or weeks for completion. Serial tests using iron-52 should considerably simplify the study of various problems such as the effects of ionizing radiations, applied generally or locally, and of cytotoxic substances on erythropoiesis. Similarly, the effect of altered physiological conditions on iron metabolism and the value of treatment techniques in cases of abnormal iron states could be elucidated.

The different physical properties of iron-52 make it possible for it to be used in conjunction with iron-59 in double labelling experiments.

We should like to thank Dr. C. A. P. Wood and Mr. G. R. Newbery for encouragement and advice. We are grateful to the cyclotron team for their work in producing the isotope. We are indebted to Mr. W. J. Dempster, Dr. I. Doniach and Dr. C. Osorio for advice and help with the animal experiments. The work of one of us (L. S.) has been conducted with the aid of a grant from the British Empire Cancer Campaign.

Use of Ion Exchange Resins in preparing Water of High Purity

A recent communication[1] directed the attention of research workers to the fact that de-ionized water could contain traces of colloidal polyelectrolytes derived from the anion exchange resin, and that the presence of such particles in the effluent could have an effect upon the properties of monolayers and impose a positive charge upon the walls of glass cells.

In the vast majority of applications the presence of minute traces of organic nitrogenous material is of no practical significance, and the remarkable ionic purity of mixed-bed de-ionized water, coupled with the ease of its preparation and its cheapness, makes it far more attractive than distilled water, which nearly always contains carbon dioxide and silica together with varying significant traces of metallic ions.

Where 'pure' water is required for work of the most critical nature, a mixed-bed ion exchange column may be used providing certain precautions are taken.

In the first place, fresh resins as obtained from manufacturers should not be used. In particular, the anion exchange resin should first be eluted and then alternately regenerated with caustic soda and exhausted with sodium chloride solution two or three times. In this way, degenerated nitrogenous materials remaining on the resin from the manufacturing process are removed. The cation exchange resins should be similarly treated by being passed through the hydrogen–sodium cycle.

After complete regeneration the resins should be thoroughly washed with distilled water (100 gallons/cu. ft. anion resin and 75 gallons/cu. ft. cation resin) at a flow rate of 0·5 gallon/cu. ft./min. and should then be intimately air-mixed in the proportion 2 anion resin : 1 cation resin, by volume.

The column should be of polyethylene, 'Perspex' or 'Pyrex' (not soda glass) and should be not less than 3 in. in diameter. A minimum of depth of bed of 24 in. should be used. In a narrow column the resin-glass interface surface–volume ratio is poor and in a short column the contact time at the optimum flow rate is inadequate. The bottom filter should be of close-woven nylon or of a similar material, or else consist of a No. 1 porosity sintered 'Pyrex' disk.

The effluent should be passed through a further small column containing sulphonated polystyrene resin in the hydrogen form cross-linked 1–2 per cent. Alternatively, the filter may take the form of a 'Pyrex' or polyethylene tube loosely packed with platinum wool maintained at a high negative potential above earth.

A particle of water introduced at the top of a column may reach the bottom in any of the following three ways: (1) by migration through the interstitial bead lattices; (2) by leakage between the beads; (3) by leakage between the resin column and the container walls.

Of these three methods of transit the first is clearly the only desirable one, and the probability of this method of transit occurring is favoured by using a column having a large volume–wall surface ratio and an adequate length.

In the lowest resin zones the column ceases to behave as a mono-bed owing to the random distribution of resin beads, with the result that binary and tertiary groups formed by the degeneration of quaternary ammonium groups may hydrolyse and go into solution. The cation resin filter will remove such components either by surface effect or by ion exchange, with the production of water. Colloidal particles of anionic resin will tend to be similarly adsorbed. Such particles will also be attracted to and retained upon a negatively charged surface.

The instructions which Mr. Raleigh has given for preparing de-ionized water of high purity are valuable and timely; they should be of interest to research workers in many fields. Evidently, with a little extra trouble one can now consistently prepare water of markedly higher purity than is commonly obtained from small laboratory mixed-bed columns, and research workers requiring water of extremely low ionic content should obviously take this extra trouble. But caution is still needed in using such water for critical studies.

First, the conductivity of the water should always be checked, using an apparatus suitable for resistivities around 5–20 megohm. cm.$^{-1}$ (which many conductivity meters are not), and its value should be stated in published work as proof of the quality of the water. The 'best' de-ionized water[1,2] has a conductivity of about 0·07 μmho cm.$^{-1}$ at 20° C., compared with 0·1–0·5 commonly obtained from small mixed-bed columns. I suggest that 'high quality de-ionized water' be defined as having a specific conductivity of not more than 0·1 μmho cm.$^{-1}$.

Secondly, our original warning[3] against the use of de-ionized water for research *in surface chemistry* must still stand, even for high-quality water. The reason is that it still contains unknown, uncontrolled traces of surface-active substances of high molecular weight. In ordinary de-ionized water these impurities can be detected by chemical analysis and by their effects on surface tension and on the surface charge of glass. The amounts present in high-quality water are doubtless much smaller, but they constitute an insidious source of danger because they can accumulate at certain surfaces. A rough calculation of the mass of a monolayer sufficient to lower the surface tension of water in a Langmuir trough by 1 dyne cm.$^{-1}$ (an easily measurable effect) shows that it amounts to only about 0·006 part per million parts of the underlying water. Since there is no means of guaranteeing absence of organic impurities down to this infinitesimal concentration (the impurities possibly including weak electrolytes), the only safe course is entirely to avoid using de-ionized water in critical research in surface chemistry. Triply-distilled water condensed in silica, having a conductivity of, say, $0\cdot3$ µmho cm.$^{-1}$, is preferable to de-ionized water of conductivity $0\cdot07$ µmho because the trace impurities in the distilled water are not highly surface-active whereas those in the de-ionized water are.

Photosynthesis of Amino-Acids from Paraformaldehyde involving the Fixation of Nitrogen in the Presence of Colloidal Molybdenum Oxide as Catalyst

APART from the various physico-chemical methods used in industry for the fixation of atmospheric nitrogen, it is well known that quite a number of micro-organisms[1] are able to fix under mild conditions a considerable quantity of atmospheric nitrogen. In this bacterial fixation, it has been observed that molybdenum takes a prominent role[2] as a catalyst.

The possibility of achieving amino-acid synthesis without the help of micro-organisms has involved also some aspects of the problem of the origin of life. Oparin[3], Urey[4] and Bernal[5] have stressed the idea that life is based upon organic compounds which were formed when methane, ammonia, water and hydrogen were the components of the atmosphere. Miller[6] succeeded in testing this hypothesis, producing amino-acids synthetically by circulating methane, ammonia, water and hydrogen past an electric discharge.

Bahadur[7] observed that when an aqueous mixture of paraformaldehyde and potassium nitrate, in the presence of ferric chloride as a catalyst, is exposed to sunlight, about a dozen amino-acids are formed in it. We have now investigated the possibility of nitrogen fixation without the help of bacteria and subsequent utilization of the fixed nitrogen in the formation of amino-acids, in an aqueous mixture containing paraformaldehyde as the source of carbon and colloidal molybdenum oxide as catalyst, by merely exposing the mixture to a 500-W. electric light.

To detect amino-acid formation, we used circular paper chromatography[8]. The sensitive ninhydrin test for amino-acids was helpful in detecting even a trace of amino-acids formed in the experiments. Heating the paper on an electric heater helped in developing the rings of even those amino-acids which were present in extremely small quantities.

Two mixtures each containing 5 gm. of paraformaldehyde, 200 c.c. of distilled water and 10 c.c. of colloidal molybdenum oxide were prepared in 500 c.c. conical flasks. The flasks were plugged with cotton-wool and sterilized. To be sure that there was no trace of any amino-acid as impurity in the mixture at the beginning, a sample of each was tested chromatographically. Both the mixtures gave negative results. One of these flasks was covered with a thick black cloth, and both were then kept 45 cm. below a 500-W. electric bulb and exposed to light for 600 hr.

After exposure, both mixtures were tested for sterility and chromatographically for the presence of amino-acids. The circular chromatograms of the mixture exposed to light showed the presence of rings with R_F values of glycine, alanine, valine, histidine, glutamic acid, aspartic acid and ornithine, according to our calibration. Of these, the glycine and alanine rings were very distinct, whereas the other amino-acid rings were faint. Chromatograms of the mixture which was kept covered with black cloth and was thus deprived of the influence of light showed extremely faint rings of glycine and alanine.

The above experiment is consistent with the hypothesis that paraformaldehyde when mixed with colloidal molybdenum oxide and water and exposed to light fixes atmospheric nitrogen, and this fixed nitrogen soon appears as amino-acids in the mixture. This conclusion is dependent on the results obtained by use of a chromatographic method which is considered quite definite for identification of amino-acids. We are trying now to provide additional evidence of amino-acid photosynthesis.

We are grateful to Dr. R. Bianco for his assistance in various phases of this work.

Influence of Amino-Acids on Actinomycin Biosynthesis

A NUMBER of nutritional and cultural factors have been shown to influence the qualitative and quantitative nature of the actinomycin mixture produced by a given *Streptomyces*[1–5]. In particular, the nitrogen source supplied may affect the composition of the complex formed[5]. Generally, it has been possible to change the proportion of any particular component in a natural mixture to a limited degree; in a few instances, however, a component normally produced in small amounts may increase to the extent that it represents the major constituent of an actinomycin complex. For example, we have observed[6] that actinomycin-V was the major component in the actinomycin mixture produced by *Streptomyces antibioticus* when L-threonine was sole nitrogen source, whereas actinomycin-IV represented the main constituent when L-glutamic acid was employed[3]. Schmidt-Kastner has shown that actinomycin-IV (C_1) increased from 10 to 83 per cent of the actinomycin mixture formed by *S. chrysomallus* when 0·5 per cent DL-valine was added to a glycerol–nitrate medium[5].

In the course of an investigation of the biosynthesis of the actinomycins produced by a strain of *S. antibioticus*, we have made observations regarding the marked influence of suitable amino-acids upon the relative amount of any one of the naturally produced actinomycins. The technique employed has been the following. Washed cells of the organism, previously grown in *N–Z* amine medium for 48 hr. on a rotary shaker at 28° C., were inoculated into a chemically defined medium composed of (per cent): D-galactose, 1·0; L-glutamic acid, 0·2; K_2HPO_4, 0·1; $ZnSO_4 \cdot 7H_2O$, 0·0025; $MgSO_4 \cdot 7H_2O$, 0·0025; $CaCl_2 \cdot 2H_2O$, 0·0025; $FeSO_4 \cdot 7H_2O$, 0·0025; distilled water, *p*H 7·2–7·3. When production of actinomycin began (1–2 days) a given concentration of an amino-acid (0·001–0·25 per cent) was added to a number of flasks of the growing culture. After an additional production period of three to seven days, the actinomycin mixture synthesized was harvested and the actinomycins present were separated by means of a circular paper chromatographic technique previously described[7]. The actinomycins separate as yellow zones on a papergram, thus facilitating their detection. The relative percentages of components in a mixture were determined by a spectrophotometric method[3].

As revealed in Table 1, actinomycin-IV represents the major component of the actinomycin complex produced by *S. antibioticus* in the glutamic acid medium. Addition to the medium of one or another amino-acid, for example, hydroxy-L-proline, sarcosine N-acetylglycine, or L-*iso*leucine, brought about significant quantitative changes in the actinomycin complex synthesized. Components normally produced in small or even trace amounts were found, under the specific conditions now employed, to represent major constituents of such mixtures. Moreover, not only was the nature of the amino-acid important, but also the level added to growing cultures was significant in bringing about the changes observed. Results obtained in an experiment using different concentrations of sarcosine are presented in Table 2.

The precise role of an amino-acid in modifying the biosynthetic reactions leading to actinomycin formation is unknown at the present time. The actinomycins represent a group of chromopeptides[8,9], and, therefore, an amino-acid might be incorporated directly into certain actinomycin peptides or be serving as a precursor for one naturally produced in limited amounts. Possibly it may interfere with the incorporation of an amino-acid into certain peptides, thereby inhibiting their formation and enabling greater synthesis of others instead[5]. Additional studies are necessary to learn how an amino-acid influences the reactions concerned with formation of this group of antibiotics.

Table 1. INFLUENCE OF AMINO-ACIDS ON ACTINOMYCIN SYNTHESIS

Medium	Concentration of amino-acid added (percent)	Relative percentage of actinomycin components					
		I	II	III	IV	V	*
1 Glutamic acid medium	0·0	6·4	2·3	3·2	68·3	17·2	2·6
2 Glutamic acid medium + hydroxy-L-proline	0·25	31·0	3·8	7·1	25·3	30·0	3·0
3 Glutamic acid medium + sarcosine	0·05	9·1	25·6	35·0	24·4	5·9	0·0
4 Glutamic acid medium + N-acetylglycine	0·25	8·1	2·0	3·2	32·7	51·1	3·0
5 Glutamic acid medium + L-*iso*leucine	0·25	4·7	2·8	5·8	17·2	30·6	38·9

* Denotes an unidentified component which moves faster than component V in circular paper chromatography.

Table 2. INFLUENCE OF SARCOSINE CONCENTRATION ON ACTINOMYCIN SYNTHESIS

Concentration of sarcosine added (per cent)	Relative percentage of actinomycin components				
	I	II	III	IV	V
0·0	6·2	2·1	2·8	80·4	8·4
0·001	5·3	9·2	11·9	63·5	10·1
0·005	6·5	21·2	30·8	35·9	5·6
0·05	9·1	25·6	35·0	24·4	5·9

A New Synthesis of the Pentapeptide L-Histidyl-L-Phenylalanyl-L-Arginyl-L-Tryptophyl-Glycine and its Melanocyte-stimulating Activity

A SYNTHESIS of the pentapeptide H.His-Phe-Arg-Try-Gly.OH along classical lines has recently been described by Hofmann *et al.*[1]. The amino-acid sequence of this peptide, which occurs in adrenocorticotropic (ACTH) and melanocyte-stimulating (MSH) hormones[2], presents a number of considerable difficulties for chemical synthesis, chiefly owing to the presence of tryptophan, arginine and histidine. In this communication, we wish to report the synthesis of this pentapeptide in a stepwise manner beginning at the C-terminus with the *p*-(*p*′-methoxy-phenylazo)-benzyloxy carbonyl group (MZ group), described by one of us[3], used as the amino-protecting agent. In addition, the *p*-toluenesulphonyl (tosyl) group was introduced to protect the guanidino group of arginine, since this protecting group resists catalytic hydrogenation and is easily removed by sodium in liquid ammonia. When the peptide was assayed either in the hypophysectomized frog or on frog skin *in vitro*, it was found to possess melanocyte-stimulating activity.

Cyanomethyl carbobenzoxy L-tryptophanate[4] was condensed with methyl glycinate to give Z.Try-Gly.OCH_3. The dipeptide ester resulting from catalytic hydrogenation in the presence of palladium was condensed with N^{α}-MZ-N^{G}-tosyl-L-arginine [prepared by treating MZ-L-arginine[3] with tosyl chloride, or by tosylating carbobenzoxy-L-arginine, removing the carbobenzoxy group and treating the N^{G}-tosyl arginine ($R_F = 0{\cdot}36$ in system A) with MZ-chloride; the product, N^{α}-MZ-N^{G}-tosyl-L-arginine: m.p. 115° C.; $[\alpha]_D = +6{\cdot}1$, 1 per cent in CH_3COOH; $R_F^A = 0{\cdot}61$ (system A), $0{\cdot}38$ (system B)] by means of reaction with dicyclohexyl carbodiimide (DCCI)[5], to give the amorphous MZ.Arg(N^{G}-tos)-Try-Gly-OCH_3, the R_F^A of which equals $0{\cdot}70$ in system A, $0{\cdot}26$ in system B, and $0{\cdot}63$ in system C. (R_F^A designates R_F values on the fully acetylated paper of Schleicher and Schuell. System A is n-BuOH/CH_3COOH/H_2O, 4 : 1 : 1; B is the lower phase of CCl_4/CH_3OH/pyridine/water, 4 : 2 : 1 : 1; C is the upper phase of this system. D is the system n-BuOH/pyridine/CH_3COOH/H_2O, 30 : 20 : 6 : 24; R_F values were obtained with Whatman No. 1 paper.) Catalytic reduction with 10 per cent palladium on charcoal in neutral solution released colourless H.Arg(N^{G}-tos)-Try-Gly-OCH_3, $R_F^A = 0{\cdot}76$ in system A and $0{\cdot}89$ in system D, which gave a positive reaction with ninhydrin and the Ehrlich reagent. This compound was combined with MZ-L-phenylalanine[3] by means of reaction with DCCI, and the product was purified in a column of acetylated cellulose (system C). MZ.Phe-Arg(N^{G}-tos)-Try-Gly.OCH_3 was obtained in crystalline form: m.p. 130° C., $[\alpha]_D = -9{\cdot}0°$, 1 per cent in CH_3COOH, $R_F^A = 0{\cdot}36$ (system C). The absorption spectrum indicates 3 peaks at 290, 350 and 430 mμ with E 9,700, 24,700 and 4,500 respectively (ethanolic solution). H.Phe-Arg(N^{G}-tos)-Try-Gly.OCH_3, obtained by catalytic hydrogenation as a colourless glassy product ($R_F = 0{\cdot}84$, system A), was further condensed with N^{α}-MZ-N^{im}-benzyl-L-histidine, giving MZ.His(N^{im}-benzyl)-Phe-Arg(N^{G}-tos)-Try-Gly.OCH_3 in the form of yellow microscopic platelets, m.p. 132° C., $[\alpha]_D - 6{\cdot}0$, 1 per cent in CH_3COOH, $R_F^A = 0{\cdot}19$ (system B); the spectrum shows 3 peaks at 290, 350 and 432 mμ with E 11,700, 31,900 and 1,640 respectively. Hydrogenation over 10 per cent palladium on charcoal and saponification with barium hydroxide yielded H.His(N^{im}-benzyl)-Phe-Arg(N^{G}-tos)-Try-Gly.OH: $R_F = 0{\cdot}68$ (system A) and $0{\cdot}92$ (system D). Treatment of this product in dry liquid ammonia at −30° C. with 20 equivalents of sodium for a short time, conversion of the resulting peptide to dihydrochloride, and extraction into glacial acetic acid gave the dihydrochloride of H.His-Phe-Arg-Try-Gly.OH as a colourless glassy product, $R_{\text{His}} = 1{\cdot}92$ (system A), which gave a positive reaction with ninhydrin and the Pauly, Sakaguchi and Ehrlich reagents; amino-acid analysis of the peptide by the Levy method[6] and by the spectrophotometric procedure of Goodwin and Morton[7] gave the molar ratio: His/Phe/Arg/Try/Gly = $0{\cdot}9/1{\cdot}1/1{\cdot}1/1{\cdot}0/1{\cdot}0$. The product was completely split by trypsin at pH 7 to give H-His-Phe-Arg-OH ($R_F = 0{\cdot}11$, system A) and H-Try-Gly-OH ($R_F = 0{\cdot}42$, system A); reaction with chymotrypsin at pH 9 resulted in total cleavage of the peptide to H.His-Phe.OH, ($R_F = 0{\cdot}11$, system A), H.Arg-Try.OH ($R_F = 0{\cdot}16$, system A) and glycine ($R_F = 0{\cdot}23$, system A).

The synthetic pentapeptide, when assayed for melanocyte-stimulating activity both on isolated frog skin[8] and in hypophysectomized *Rana pipiens*, was found to possess an activity of 3 × 10^4 MSH units per gm. A hexapeptide, H-Glu-His-Phe-Arg-Try-Gly.-OH, synthesized by H. Kappeler in the laboratory of one of us (R. S.) at Basle by conventional coupling of Glu, His-Phe-Arg, and Try-Gly, has been assayed for MSH activity and found to be more active (2 × 10^5 units per gm.) than the pentapeptide herein reported. It is of interest to note that Hofmann *et al.*[9] reported the synthesis of an octapeptide, H.Ser-Met-Glu(NH_2)-His-Phe-Arg-Try-Gly.OH, with an MSH activity of 7 × 10^5 units per gm. When solutions of the synthetic product (1 mgm./ml.) in $0{\cdot}1$ M sodium hydroxide were kept at 100° C. for 15 min., the resulting products exhibited the characteristic 'prolongation' activity in hypophysectomized frogs found in MSH and ACTH preparations[2] that have been treated in a similar manner. Analysis by the Levy procedure[6] of the pentapeptide after alkali-heat treatment showed that the arginine residue has been partially converted into ornithine. (Earlier preliminary studies with I. I. Geschwind using MSH, ACTH and crude peptide preparations gave similar conclusions.) Whether or not the 'prolongation' effect is due solely to the modification of arginine in the peptide remains to be investigated. Further studies of these problems are in progress.

This work is supported in part by the U.S. Public Health Service (*G*–2907). The synthesis was carried out by one of us (R. S.), and we wish to acknowledge the able assistance of D. Chung and W. Lilly in the course of these investigations.

Determination of Indole Acetic Acid by the Salkowsky Reaction

RECENTLY attention has been focused on the reaction of indole acetic acid with ferric ions. Cohen *et al.*[1] have shown that indole acetic acid forms a chelate with iron at acid pH and this has been confirmed by Recaldin and Heath[2]. The latter state that at pH $2{\cdot}6$ iron slowly decomposes the indole acetic acid in the solution. The oxidation of indole acetic acid by ferric salts is the basis of the colorimetric determination of the acid based on the Salkowsky reaction[3–5]. It is generally supposed that these reactions measure the formation of a coloured oxidation compound of indole acetic acid formed at very acid pH in the presence of ferric chloride.

Chance observation in this laboratory (by Blumenthal-Goldschmidt) showed that the usual Tang–Bonner reagent gives a different and stronger colour

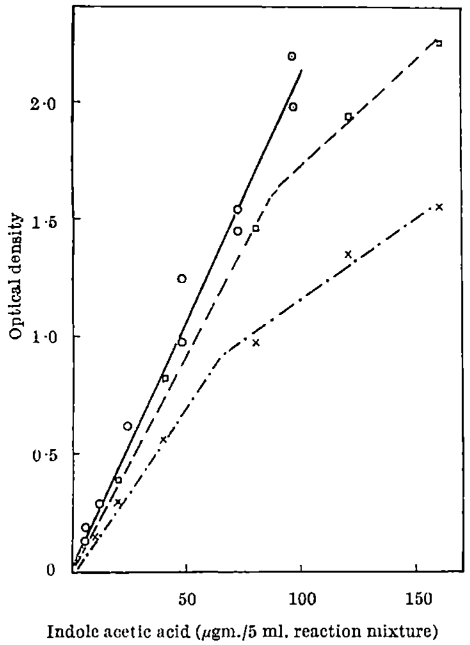

Fig. 1. Relation between concentration of indole acetic acid and intensity of colour as produced by various reactions. ×—×, Tang–Bonner reagent, optical density at 530 mµ; □—□, reagent prepared with trichloroacetic acid, optical density at 545 mµ; ⊙—⊙, reaction for ferrous iron produced by oxidation of indole acetic acid, optical density at 730 mµ

with indole acetic acid in the presence of trichloroacetic acid. This reaction has been investigated in greater detail. It was found that a reagent for indole acetic acid could be prepared in 5·6 *N* trichloroacetic acid containing 30 ml. of 0·5 *N* ferric chloride per 800 ml. trichloroacetic acid, which gives a stronger stable colour with indole acetic acid under the same conditions as the Tang-Bonner reagent[4]. The absorption maximum of this compound was slightly different from that of the Tang–Bonner reagent, namely, at 545 mµ. A comparison of the two reactions is shown in Fig. 1. The trichloroacetic acid reagent shows the same break in linearity of relation between concentration and colour as does the Tang–Bonner reagent[4] and that of Gordon and Weber[5].

It seemed of interest to determine the fate of the iron during the Tang-Bonner reaction. Possibly ferric iron is quantitatively reduced to ferrous iron. 1 ml. of Tang–Bonner reagent was added to suitable samples of indole acetic acid in 1 ml. water and the reaction mixture allowed to stand for half an hour at room temperature. At the end of this period 6 ml. of 0·2 per cent potassium ferricyanide (freshly prepared in boiled distilled water) was added and the mixture was allowed to stand for a further half-hour. The intensity of the bluish-green colour of Turnbull's blue was measured at 730 mµ. As will be seen from Fig. 1, a straight-line relationship exists between the intensity of the colour and the concentration of indole acetic acid in the reaction mixture. The breaks occurring with the other reactions do not appear.

It seems clear that, under the conditions used, indole acetic acid reduces ferric iron quantitatively to the ferrous state. The breaks in the curves with the Tang–Bonner and similar reagents must be due to changes occurring in the oxidation product of indole acetic acid. The estimation of ferrous iron formed due to the interaction of ferric iron with indole acetic acid could form the basis of a quantitative determination of the latter.

The Spontaneous Change of Ferriprotoporphyrin in Alkaline Solution

THERE are repeated suggestions in the literature that ferriprotoporphyrin in alkaline solution is unstable. Haurowitz[1] observed a decreased diffusion rate with time, and Shack and Clark[2] noted changes in the visible spectrum. Both these observations were interpreted as resulting from an increase in particle size. Rosenfeld and Surgenor[3] found that ferriprotoporphyrin could be separated from the alkaline conversion product by differences in solubility in the two-phase system, *n*-butanol and *p*H 9·6 bicarbonate buffer. In spite of these and other observations, the nature of the reaction remains unknown. In this communication we present spectrophotometric evidence that a chemical change occurs in ferriprotoporphyrin on standing in an aerated alkaline solution, and that the change is probably a modification of the vinyl side-chains.

We have found that in the presence of air and in 0·1 *N* sodium hydroxide the Soret peak of a 10^{-5} *M* solution of ferriprotoporphyrin decreases about 30 per cent in 20 days and then very little more with additional time. This coincides with the change in the visible absorption spectrum observed by Shack and Clark[2]. The rate of the reaction is affected by the concentration of sodium hydroxide. For a 10^{-5} *M* solution of ferriprotoporphyrin the decrease in the Soret peak in 12 days was about 29 per cent for 0·1 *N* sodium hydroxide, 13 per cent for 0·01 *N*, and 6 per cent for 0·001 *N*. Substances which coordinate with iron also reduce the rate of the reaction (Table 1). The rate is very greatly decreased when the iron is complexed with cyanide or pyridine as it is in 0·5 *M* potassium cyanide and 1·2 *M* pyridine[4].

The alkaline conversion product was prepared by storing ferriprotoporphyrin in 0·1 *N* sodium hydroxide for at least three weeks. The *p*H was reduced to 9·6 with carbon dioxide, and unchanged ferriprotoporphyrin was extracted with butanol[3]. The pigment was precipitated from the buffer solution with acid and thoroughly washed with water, alcohol and ether.

To show that the iron atom had not been altered in some way during the reaction it was removed by

Table 1. EFFECT OF ADDITIVES ON SPONTANEOUS CHANGE OF 10^{-5} *M* FERRIPROTOPORPHYRIN IN 0·1 *N* SODIUM HYDROXIDE

Final concentration (*M*)	Additive	Per cent decrease Soret peak at 13 days

0·5	,, ,,	2
1·2	Pyridine	2

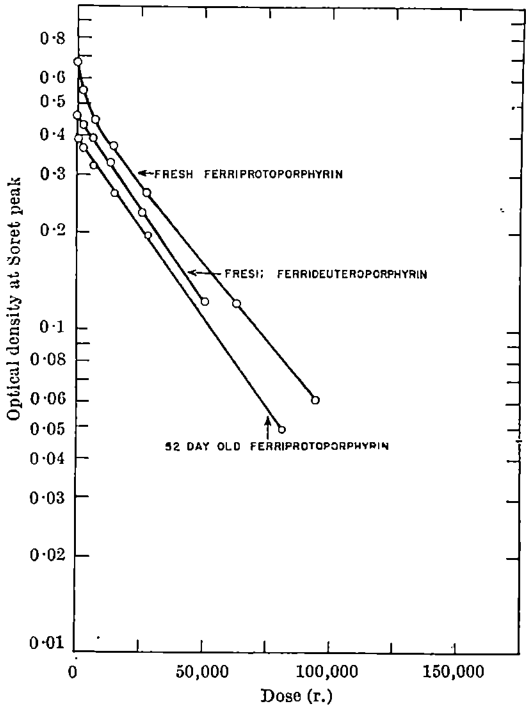

Fig. 1. Gamma irradiation of ferriprotoporphyrin

the method of Morell and Stewart[5]. The resulting porphyrin had absorption maxima in glacial acetic acid 4 mμ toward shorter wave-lengths than protoporphyrin. The porphyrin also differed from protoporphyrin in that most of the pigment precipitated from an ether–acetic acid solution when the acetic acid was extracted.

This slight shift toward shorter wave-lengths also occurs in the spectra of the reduced cyanide and pyridine derivatives of the alkaline conversion product. The maxima in 25 per cent aqueous pyridine and dithionite are at 522 and 552 mμ and in 0·5 *M* potassium cyanide, 0·1 *N* sodium hydroxide and dithionite at 536 and 564 mμ. The corresponding ferriprotoporphyrin derivatives are at 525 and 556 mμ and at 538 and 568 mμ, respectively. Since the position of the visible absorption peaks of such derivatives of ferroporphyrins has been deduced by Drabkin[6] to be attributable to the nature of the side-chains in the 2 and 4 position, the spectral data then suggest that the vinyl groups have been altered.

Further evidence that the vinyl side-chains are involved can be found by comparing the 'ageing' reaction with the irradiation reaction[7]. The change in the visible absorption spectrum of ferriprotoporphyrin in 0·1 *N* sodium hydroxide after standing 20 days is very similar to the change after exposure to 15,000 r. of gamma radiation. The absorption peaks of the alkaline conversion product in 25 per cent pyridine and dithionite are also at almost the same wave-lengths as those of the pigment from irradiated ferriprotoporphyrin in the same solvent. If the reaction in alkaline solution with time is the same as that resulting from 15,000 r., then irradiation of an 'old' solution of ferriprotoporphyrin in 0·1 *N* sodium hydroxide should result only in the second phase of the irradiation reaction. Fig. 1 shows the decrease of the Soret peak with increasing doses of gamma radiation for a sample of a freshly prepared solution of ferriprotoporphyrin in 0·1 *N* sodium hydroxide and for a 52-day-old sample of the same solution. The decrease is exponential throughout for the old solution, and the rate is about the same as that of the exponential decrease of the fresh solution. Also shown in Fig. 1 is the decrease in the Soret peak of ferrideuteroporphyrin in 0·1 *N* sodium hydroxide. Here, too, the rate of decrease is exponential. Furthermore, unlike ferriprotoporphyrin, the absorption spectrum does not change when ferrideuteroporphyrin in 0·1 *N* sodium hydroxide is kept for 6 months. From this, and the evidence in Table 1, it clearly follows then that the vinyl side-chains as well as an uncomplexed central iron atom are necessary for the reaction. The iron apparently is involved in an intermediate step, whereas the observed chemical change seems to be due to an alteration of the vinyl side-chains. No evidence has been obtained as yet concerning the molecular weight of the alkaline conversion product. Polymerization of various vinyl compounds is well known[8] and this would be consistent with the observation of Haurowitz[1].

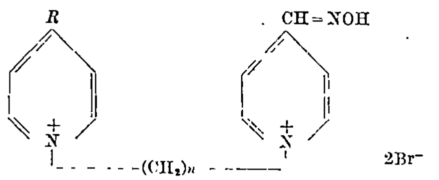
Protection by Oximes of *bis*-Pyridinium Ions against Lethal Di*iso*propyl Phosphonofluoridate Poisoning

THE monoximes and dioximes of *bis*-pyridinium ions are considerably more effective than any other known compound in re-activating acetocholinesterase inhibited by tetraethyl pyrophosphate and in protecting mice against lethal tetraethyl pyrophosphate poisoning[1]. Equally favourable results have now been obtained in experiments in which di*iso*propyl phosphonofluoridate was used instead of tetraethyl pyrophosphate. Tables 1 and 2 show the effectiveness (relative to pyridine-2-aldoxime methiodide) of four oximes of *bis*-pyridinium ions in restoring the activity of acetocholinesterase freshly inhibited by di*iso*propyl phosphonofluoridate, and the protection given by 0·095 m.mole/kgm. of the same compounds against lethal poisoning by di*iso*propyl phosphonofluoridate in mice. Results obtained with three other compounds, a monoxime ($n = 5$) and two dioximes ($n = 2$ and 5), are not included in Tables 1 and 2 because they are inferior to compounds 1–4 as regards therapeutic ratio or water solubility.

Table 1



Compound			Potency as reactivator relative to pyridine-2-aldoxime methiodide (*P*–2–*AM*)
Code number	*R*	*n*	
1	H	3	11
2	H	4	10
3	CH=NOH	3	52
4	CH=NOH	4	38
P–2–*AM*	—	—	1

The method used to determine the potency of the oximes as reactivators was the same as that used previously (ref. 1).

Table 2. PROTECTION AGAINST LETHAL POISONING BY DI*iso*PROPYL PHOSPHONOFLUORIDATE

Male white mice weighing between 18 and 20 gm. were injected intraperitoneally with 0·2 ml. of the oxime in 0·9 per cent sodium chloride solution and then 5–8 min. later they were injected subcutaneously with 0·2 ml. di*iso*propyl phosphonofluoridate in 0·9 per cent sodium choride solution. 0·095 m.mole/kgm. of the oximes, that is, 25 mgm./kgm. in the case of pyridine-2-aldoxime methiodide, were used and mice injected with the oximes alone showed no symptoms

Compound	No. of mice surviving for 24 hr./No. of mice injected					
	mgm. Di*iso*propyl phosphonofluoridate injected per mouse					
	0·1	0·15	0·2	0·4	0·8	1·6
—	6/6	2/6	0/6			
1			6/6	6/6	2/6	0/6
2			6/6	4/6	0/6	
3			6/6	6/6	3/6	0/6
4			6/6	5/6	1/6	0/6
P–2–*AM*		6/6	2/6	0/6	0/6	

A more detailed study of the antidotal properties of compounds 1 and 3 in mice showed that they raised the *LD*50 of di*iso*propyl phosphonofluoridate 1–2 and 2–3 fold respectively when used in a dose of 0·0095 m.mole/kgm. under conditions described in Table 2. The effect of the two oximes was potentiated by 1 mgm./kgm. atropine sulphate (given intraperitoneally 15 min. before the oxime). Such a dose of atropine had no antidotal effect itself but, when used in conjunction with 0·0095 m.mole/kgm. of compounds 1 and 3, raised the *LD*50 of di*iso*propyl phosphonofluoridate by 2–3 and 5–7 fold respectively.

Partial reactivation of di*iso*propyl phosphorylacetocholinesterase in blood but not in brain was recorded in mice which received a subcutaneous injection of 2·5 mgm./kgm. di*iso*propyl phosphonofluoridate, followed 30 min. later by an injection of 0·095 m.mole/kgm. of compound 3. These findings show that the oximes of *bis*-pyridinium ions act predominantly peripherally and that the mechanism responsible for their antidotal action involves reactivation of the phosphorylated acetocholinesterase.

It has previously been shown that the di*iso*propyl phosphorylacetocholinesterase formed initially has an approximate half-life of 4 hr. and changes into a phosphorylated enzyme which cannot be reactivated by pyridine-2-aldoxime methiodide[2]. The oximes of *bis*-pyridinium ions also fail to restore the activity of the phosphorylated enzyme resistant to pyridine-2-aldoxime methiodide, and thus marked therapeutic effects of compounds 1–4 will only be obtained when they are administered within a few hours following exposure to di*iso*propyl phosphonofluoridate. Keeping this limitation in mind, it seems that the results obtained raise the hope that a really effective causative treatment of poisoning of man by tetraethyl pyrophosphate, di*iso*propyl phosphonofluoridate and related organophosphates might soon become available.

One of us (P. W. S.) wishes to thank the Department of Scientific and Industrial Research for a special research grant that has defrayed some of the cost of this work.

Myasthenic-like Features of Neuromuscular Transmission after Administration of an Inhibitor of Acetylcholine Synthesis

IT has been suggested that a defect of acetylcholine synthesis in motor nerve endings would account best for the peculiar features of neuromuscular block seen in myasthenic patients[1]. This hypothesis can be tested by investigating the effect on the skeletal muscle of the cat of a recently developed drug[2], hemicholinium base *HC*3, which strongly inhibits the synthesis of acetylcholine by nervous tissue[3].

Fig. 1 presents typical observations from a myasthenic patient free from any drug (*B*), a cat treated with hemicholinium *HC*3 (*C*), and another cat mildly paralysed with *d*-tubocurarine (*D*). What is being compared is the pattern of changes in neuromuscular block following a brief faradization of the motor nerve. The amount of block is estimated by delivering supramaximal shocks at 3/sec. to the motor nerve and recording the integrated electrical response of the muscle with belly-tendon electrodes. The responses at 3/sec. exhibit a typical decrement in partially curarized muscle[4], in myasthenic muscle[5,6] and also in muscle treated with hemicholinium. I find that the percentage reduction of, say, the fifth response of the 3/sec. train with respect to the first response (*b* : *a*, in Fig. 1,*A*) is a very sensitive and reliable test of synaptic failure in the three conditions which are being compared.

The post-tetanic effects shown in Fig. 1,*B* are similar to those previously described for another myasthenic[6] and they are typical of the syndrome. In the 3/sec. test-trains elicited every minute or so, the fifth potential is about 66 per cent of the first in this case (see diagram). After faradization, a short-lived facilitation appears, followed by a prominent phase of post-tetanic exhaustion (3 min. after tetanus, fifth potential in the test-train is 29 per cent of first) which is dissipated in the following 15–20 min. This enduring increase in neuromuscular block is obviously the analogue of the long-lasting component of the pathological fatigue seen clinically in these patients[6].

The neuromuscular defect produced by hemicholinium *HC*3 in cat's muscle is peculiar: intravenous injection of the drug does not produce any failure of the indirect response until after the motor nerve has been repeatedly stimulated and the stocks of preformed transmitter have thereby presumably

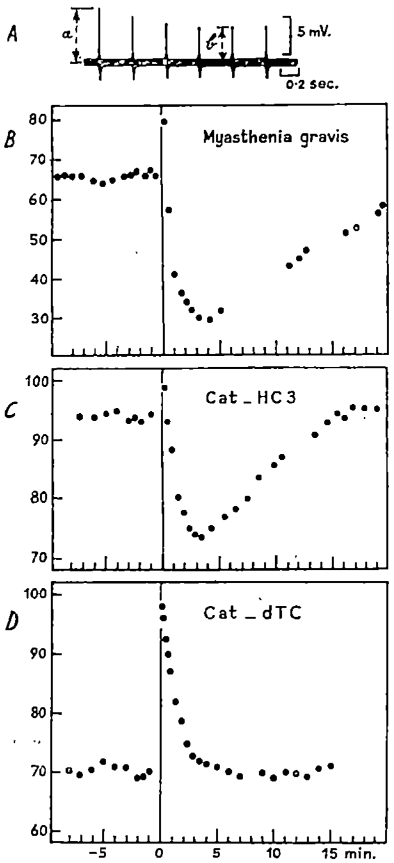

Fig. 1. In each diagram the abscissa represents time in minutes following (or preceding) faradization of motor nerve. The ordinate represents the percentage reduction of the voltage of the fifth response in a 3/sec. test-train with respect to the voltage of the first response in same train; this percentage decrement is proportional to the amount of neuromuscular block. The procedure used to estimate the decrement is illustrated on an actual record from myasthenic muscle in *A*.

B, Myasthenic patient never treated with drugs up to the time of the experiment. Results from adductor pollicis muscle stimulated supramaximally through ulnar nerve. Intramuscular temperature, 36·3° C. At zero time the ulnar nerve is faradized at 50/sec. for 2 sec.

C, Cat, 3 kgm., anæsthetized with chloralose. Hemicholinium base *HC*3 injected intravenously 1 hr. before (1·5 mgm./kgm.). Results from tibialis anticus muscle stimulated supramaximally through peroneal nerve. Intramuscular temperature, 33·2° C. Rectal temperature, 37° C. At zero time the nerve is faradized at 50/sec. for 10 sec.

D, Cat, 2·2 kgm., anæsthetized with chloralose. A constant intravenous infusion of *d*-tubocurarine ('Intocostrin', Squibb) maintains a steady state of partial curarization. Data from tibialis anticus muscle stimulated supramaximally through peroneal nerve. Intramuscular temperature, 34° C. Rectal temperature, 36·2° C. At zero time the nerve is faradized at 50/sec. for 3 sec.

been depleted. In the experiment illustrated (Fig. 1,*C*) about 5,000 shocks had been delivered to the motor nerve during the hour following injection of 1·5 mgm./kgm. hemicholinium *HC*3. At the beginning of the diagram, a small decrement is seen in the 3/sec. test-train, the fifth response being 93 per cent of the first. After faradization, a short-lived facilitation appears, followed by a considerable deepening in the neuromuscular block (3 min. after tetanus, the fifth response in the test-train is only 73 per cent of first). This 'post-tetanic exhaustion' is dissipated in about 15 min.

In contrast with the above, the muscle partially paralysed with *d*-tubocurarine (Fig. 1,*D*) does not show any increase in the amount of block after faradization. There appears only the well-known facilitation of transmission which is dissipated in the 3–5 min. following the 50/sec. tetanus.

The post-tetanic effects recorded in myasthenic patients free from any drug and in the cat's muscle treated with hemicholinium thus appear strikingly similar, and they differ completely from what is observed in partially curarized muscle. It is suggested that the pattern of these effects results from the interaction of two opposing processes with different time-courses: (*a*) facilitated ejection of acetylcholine from nerve endings which lasts about 4 min. after a 50/sec. tetanus, and (*b*) depletion of stocks of preformed acetylcholine in nerve endings. In normal or curarized muscles, synthesis of transmitter would roughly keep pace with ejection provided physiological rates of stimulation (less than 50/sec.) are used. By contrast, in myasthenic muscles or in muscles treated with hemicholinium, such quick restoration could not occur, and the facilitation of the release of acetylcholine would only transiently mask the depletion (see ref. 1).

The evidence presented strongly supports the suggestion that the myasthenic condition results from a presynaptic biochemical defect chronically impairing synthesis of acetylcholine. However, the experiments do not indicate which step in the process may be disorganized (such as cholinacetylase deficiency, impaired choline transport, etc.). Finally, it is thought that a lasting alteration in presynaptic function might induce secondary changes in motor end-plate behaviour, which would account for the changed reaction to drugs described by others[7].

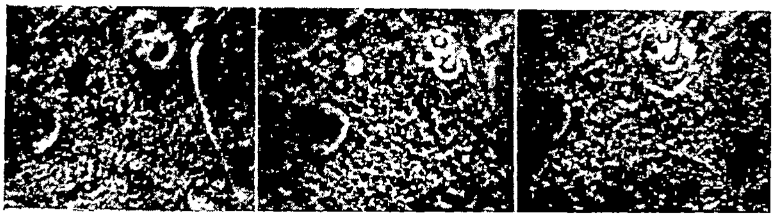
Effect of Adrenaline on Neurofibril Formation in Adult Mammalian Cortical Neurones in Tissue Culture

In recent experiments, the addition of adrenaline (0·001–0·005 μgm./ml.) to *in vitro* cultures or subcultures of adult mammalian cerebral cortex invariably caused the appearance of neurofibrils in the neurones within 30–90 min. The formation of neurofibrils was recorded, with phase-contrast time-lapse photomicrography, on the living neurones.

The occurrence of neurofibrils in tissue cultures has been described by Levi and Meyer[1] and Weiss and Wang[2] in ganglion cells of chick embryos. They could be seen with greater frequency in fixed and stained preparations than in living cells. Similar observations were made by R. S. Geiger[3] on cultures and subcultures of adult mammalian cerebral and cerebellar cortex.

Almost immediately after the addition of adrenaline to the cultures, the optical density of various nucleolar and other nuclear areas started to change. Fibrils



(a) (b) (c)

Fig. 1. Single frames from time-lapse ciné film, ×133 phase-contrast of cell body of a large pyramidal neurone from the cerebral cortex of adult rabbit, second subculture, 68 days in culture. (a) 60 min. after addition of 0·001 μgm./ml. adrenaline; (b) 90 min. after addition; (c) 120 min. after addition

appeared first at the nucleoli, often as a beaded chain, and from there extended gradually into the nucleoplasm and cytoplasm. They wound first around the nucleus, then spread into the remainder of the cytoplasm, the dendrites and axon. They gradually became thicker, and in large neurones often appeared as tangles of thread. Cytoplasmic granules usually surrounding the nuclear boundary dispersed irregularly. About one hour after the addition of adrenaline many large aggregates of granules were seen in the cytoplasm and dendrites.

The nucleoplasm condensed towards the nucleoli, often surrounding them with a ring consisting of material of high optical density. Both nuclei and nucleoli showed patches of varying densities, some areas appearing completely clear. The neurofibrils always appeared first at the nucleolus. The areas from which the fibrils originate are strongly osmophilic and they increase in size as fibril formation proceeds (Figs. 1 and 2).

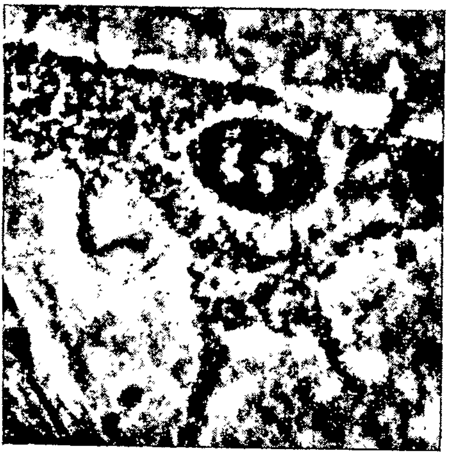


Fig. 2. Neurone from second subculture cerebral cortex of adult rabbit, 72 days in culture, exposed to 2 per cent osmic acid vapour for 30 min., 60 min. after addition of adrenaline, 0·001 μgm./ml.

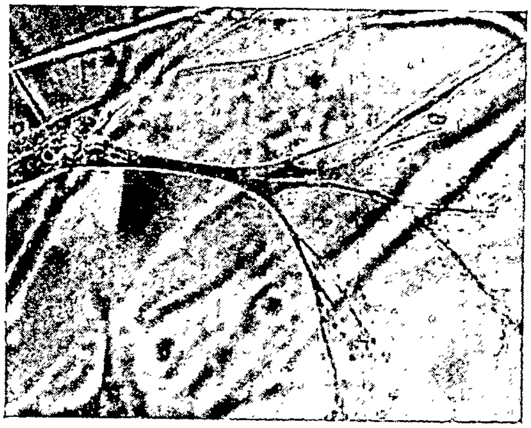

Fig. 3. Neurone from second subculture cerebral cortex of adult rabbit 20 hr. after addition of adrenaline, 0·001 μgm./ml. (× 125) photographed with ordinary light

One to two days after addition of adrenaline, even if neurofibril formation is still progressing, the nucleus assumes a more normal or resting appearance, the nucleoplasm as a whole appears more uniform, as does the nucleolus, which becomes smaller (Fig. 3.)

The osmophilic areas of the nucleoli also take up janus green *B* (conc. 1 : 150,000) and this janus green *B* staining material is associated with the newly formed fibrils in the nucleus. Janus green *B*, although toxic to neurones, causing chromatolysis and degeneration often within 24 hr., did not inhibit neurofibril formation in the cultures treated with adrenaline. The findings of Allfrey and Mirsky[4] that janus green *B* does not inhibit synthesis of adenosine triphosphate by isolated thymus nuclei, although it inhibits it in mitochondria, may be relevant here.

In the cytoplasm of neurones vitally stained with janus green *B* and neutral red, both the mitochondria and neutral red-staining granules are intermingled with fibrils. However, after chromatolysis sets in, many of the neutral red-staining granules disappear and the mitochondria are seen at the border of the vacuoles, disassociated from the fibrils. The neurofibrils remain visible throughout the neuroplasm, and are separated from other organelles.

I wish to thank N. A. Bartley for assistance in photomicrography, and the Department of Public Welfare of the State of Illinois for its support.

Plateau Formation and Sulphydryl Groups in the Plasma Membrane

It is well known that there are two types of the action potential. The difference between these is principally due to the degree of plateau formation. The modern sodium theory of Hodgkin and Huxley describes faithfully the initial phase of action potential, but the interpretation of the recovery phase in terms of the sodium theory met with many difficulties[1]. To obtain more accurate knowledge of the action potential, we have studied the mechanism of plateau formation.

Experiments were made on myelinated nerve fibres and ventricle muscle fibres of the Japanese toad. To detect the action current of a single isolated nerve fibre, Tasaki's air-gap method[2] was employed. The action potentials of single isolated cardiac muscle fibres were recorded electrically with intracellular micro-electrodes[3].

When the myelinated nerve fibre was treated with various divalent metallic ions or with some oxidizing agents, such as *p*-quinone and hydrogen peroxide, a

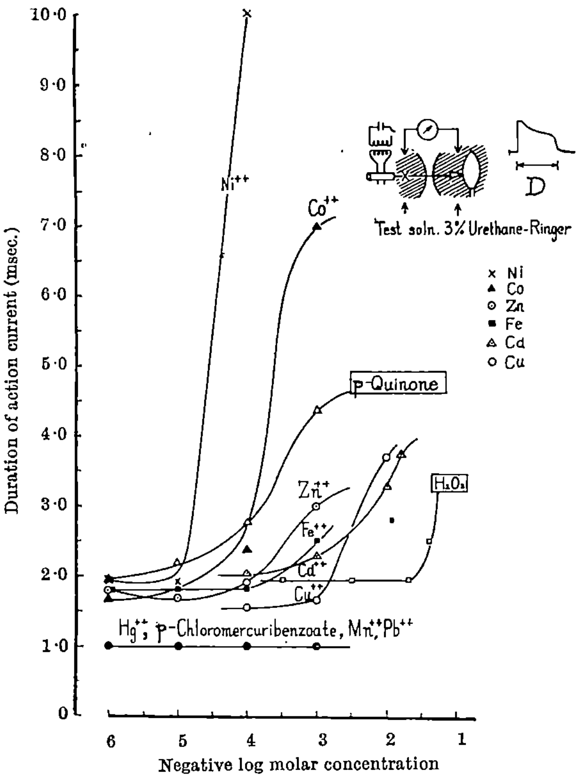

Fig. 1. Plateau-forming action of various agents

marked plateau appeared in its action current. In Fig. 1, the duration of action currents is plotted as a function of the concentration of their effectors.

The plateau formation disappeared completely on the addition of cysteine (Fig. 3,*a*). With this cysteine recovery, the plateau-forming strength of each metallic ion could be compared in the same preparation. Their relative strengths in 10^{-3} *M* were as follows: iron, copper, zinc and cadmium, 0·1–0·2; cobalt, 1·0; nickel, 3·0–4·0.

Within limits, the duration of the plateau was prolonged with increase in the concentration of the agents, but high concentrations of the agents rather tended to curtail the plateau. In Fig. 2 this effect is shown for cobalt as an example. The optimal concentration for plateau formation by cobalt and nickel ions was 10^{-3} *M* (Fig. 3,*b*).

On the other hand, the effect of agents at high concentration was reversed by washing with fresh Ringer or by the addition of cysteine at a relatively low concentration.

p-Chloromercuribenzoic acid ($10^{-6} - 5 \times 10^{-4}$ *M*) did not show any appreciable plateau formation. But it could inhibit strongly the plateau formation of cobalt or nickel ions.

Anoxia and various metabolic inhibitors (fluoride, monoiodoacetate, phlorizin, malonate, cyanide, azide, dinitrophenol, arsenite, arsenate, etc.) did not change the wave configuration of the action current. Consequently, plateau formation in a single nerve fibre is not due to the inhibition of metabolism.

Our findings can be explained by assuming that plateau formation in the action current is due to —S—*Me*—S— linkage (where *Me* is a divalent metal) of sulphydryl groups in the plasma membrane (presumably in the membrane protein) and that Cl—*Me*—S— is inactive in plateau formation.

In the toad's heart muscle, the action potential of which shows a marked plateau, it was reported by Takahashi *et al.*[4] that the plateau was curtailed reversibly by SH-reagents. Fig. 3,*c* shows that curtailment of the plateau can be brought about by cadmium ions without changes in spike height or in resting potential.

These findings suggest that in the cardiac muscle fibre, sulphydryl groups are present mainly in the

Incorporation of Manganese into Erythrocytes as Evidence for a Manganese Porphyrin in Man

MANGANESE is established as an essential constituent of the body. Kinetic studies[1] have shown this element to exist predominantly in a labile, easily exchangeable form. Natural organometallic compounds of manganese have not been identified in vertebrates.

Manganese has been assumed to participate indirectly in hæmatopoiesis[2]. Natural porphyrins are known which are bound to metals other than iron[3] (namely, vitamin B_{12} and chlorophyll). Nevertheless, manganese has not been implicated hitherto in the structure of either the erythrocyte or the respiratory pigments. The present results show a firmly bound manganese component in human and rabbit erythrocytes which appears in good yield in the crystallized hæmin fraction, suggesting that it may have a role in the porphyrin metabolism of cells.

Following the injection into patients of carrier-free manganese-54 (half life, 300 days), the kinetics of the initial venous blood clearance were entirely consistent with the patterns previously reported[1] for the short-lived isotope, manganese-56. The use of a single-channel pulse height analyser provided measurements of the venous blood and plasma manganese-54 even after the first several hours, when readings on conventional scintillation counters had fallen to statistically insignificant levels. With this method, the radioactivity in blood was lowest 36–48 hr. after intravenous injection, followed by a rise over the next week or ten days to a plateau value (Fig. 1). Centrifugation of the blood samples showed this biphasic response to represent two separate processes: (*a*) rapid disappearance of radioactivity from plasma and (*b*) slow appearance and retention in circulating erythrocytes (Fig. 1).

Blood taken from a patient 66 days after injection of manganese-54 contained almost the entire radioactivity in the red cell fraction. (There was no selective concentration of manganese-54 in the buffy coat.) Repeated washing with saline failed to elute the isotope, and when the cells were hæmolysed with 7 volumes of distilled water, there was insignificant accumulation of tracer in the packed stroma ('ghosts'). The rigorous dialyses summarized in Table 1 failed to remove any appreciable amount of radioactivity from hæmolysates tested directly, indicating that the metal was non-dialysable, non-exchangeable, and not available for chelation with disodium ethylenediamine tetraacetic acid.

This incorporation of manganese-54 into red cells *in vivo* was quite distinct from the uptake of isotope by the cells *in vitro*. Agitation of blood with carrier-free $^{54}MnCl_2$ at room temperature for 18 hr. showed relatively little binding by erythrocytes, and most of the activity then bound was eluted readily with saline washes. On hæmolysis the tracer concentration in the stroma was 2·5 times higher than that in the hæmolysate, and dialysis was extremely effective in removing manganese-54 from the hæmolysate (Table 1). These experiments indicated that traces of manganese added *in vitro* to mature erythrocytes or their hæmolysates were bound relatively weakly and primarily to the stroma, in contrast to the physiologically deposited manganese, which was incorporated into a structural component of the hæmolysate.

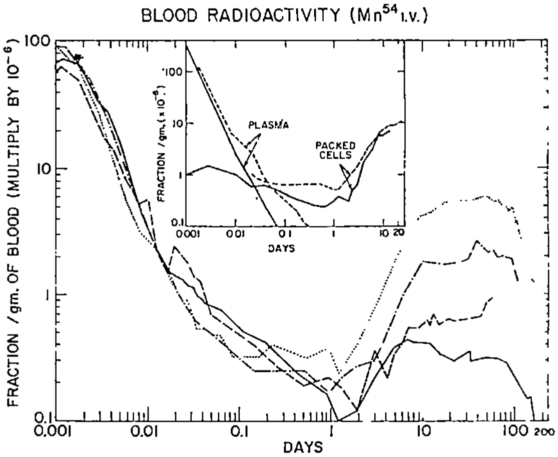

Fig. 1. Time-curves of venous blood radioactivity following intravenous injection of $^{54}MnCl_2$ into several patients. Ordinate values represent the fraction of administered manganese-54 per gm. (of whole blood, plasma, etc.) corrected to 70 kgm. of body-weight. Insert shows detailed behaviour of centrifuged blood fractions in two representative cases, wherein the packed cells have been washed twice in saline

The time-course of the reappearance of manganese-54 in blood (Fig. 1) is similar to that which follows iron-59 injections[4]. It resembles even more closely the time-curve[5] of protoporphyrin labelled with nitrogen-15. Therefore this phenomenon may indicate the synthesis of a manganese porphyrin. Experiments with both human and rabbit blood showed that the incorporated radiomanganese was isolated predominantly in the crystallized hæmin[6]. The high acidity of the media employed for crystallization favoured solubilization of manganese porphyrins and precipitation of iron porphyrin[7]. Even so, successive recrystallizations showed a relatively small

fall of radioactivity per unit weight of hæmin, indicating that in all probability the manganese organometallic compound under study is indeed a porphyrin. Experiments are now in progress to characterize this manganese-porphyrin complex more precisely.

Effect of Viral Infection and Cortisone upon Tumour Growth in Homologous and Heterologous Hosts

RECENTLY, human tumours have been successfully transplanted to rats and hamsters conditioned with X-ray and/or cortisone, and several cell lines are now available for use in studying the effects of chemotherapeutic agents or viruses on them[1–4]. Human tumour HeLa cells, grown in tissue culture, have also been transplanted to conditioned rats and their viral susceptibility examined[5]. However, the problem of whether experimental results obtained by using tumours transplanted to a heterologous host, such as a hamster, could be applied directly to cancer in human beings or not remains to be solved. In the present communication, a transplantable mouse tumour is adopted as an experimental model and the interaction of extraneous viruses and tumour in homologous and heterologous hosts is examined, together with the effect of cortisone upon tumours in different host species.

Fructose sarcoma was chiefly used as before[6]. Fragments of the tumour were transplanted into the subcutaneous space of the back of mice and to one or both sides of the breast of rats, using a trochar. Rats, weighing about 80 gm., were treated with 5 mgm. of cortisone just after tumour transplantation and received two to three additional injections of 5 mgm. at four day intervals. Sarcomas in rats treated with cortisone attained the size of 2·0 cm. × 1·5 cm. within ten days. Mice were not treated with cortisone. About a week after tumour transplantation, 10^{-5} dilution of Col-*SK* virus was injected directly into tumours in mice and in rats. On the second and fourth or fifth day after virus inoculation, tumours were extirpated and their *LD*50 measured by intracerebral titration in mice. As shown in Fig. 1*a*, the infectious titre of the virus in tumours grown in rats was always higher than that grown in mouse tumours. In such instances, the growth of virus-infected and control tumours in mice was almost the same, but in rats treated with cortisone there were distinct differences: namely, in rats the sarcoma continued to grow for 3–4 days after virus inoculation and then it began to regress, whereas non-infected tumour did not usually show any sign of regression as long as cortisone treatment was continued. The fact that virus-infected sarcoma does not regress in mice, but does regress in rats, suggests that immunological host factors are operating. In rats without cortisone treatment, the sarcoma often began to regress about 12 days after transplantation. Thus the immunological responses of the host against heterologous tissue may act in addition to the cytopathic effect of virus in causing tumour regression.

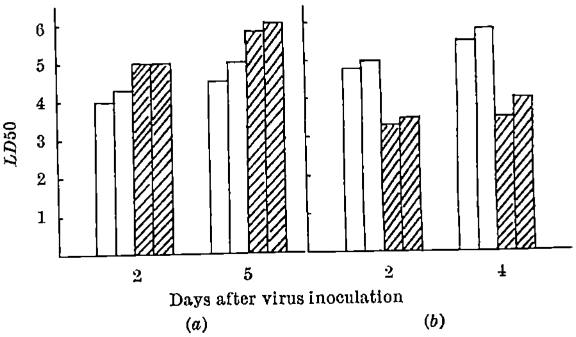

Fig. 1. Propagation of (*a*) Col-*SK* virus and (*b*) *WEE* virus in sarcomas grown in mice and rats. Unshaded, mice; shaded, rats

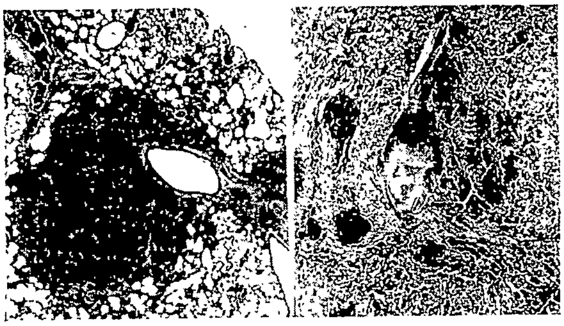
The same experiments were performed using Western equine encephalomyelitis virus (Fig. 1*b*). Here, the virus titre in tumours grown in rats was lower than in those grown in mice, and tumour development was not impaired in rats as it was in mice, despite virus propagation[7]. Thus, the multiplication of extraneous viruses in tumours grown in homologous and heterologous hosts depends on the host animal. In other experiments, we transplanted Rous sarcoma into chickens and cortisone-treated hamsters, and compared the tumour sizes and virus yields. Though the size of the tumours in hamsters was much smaller than in chickens, virus yield was equal to or greater than from sarcomas in chickens[8]. On the other hand, Chaproniere and Andrewes[9] reported that the myxoma virus of the rabbit multiplies in homografts of tissues from normally resistant species, such as the guinea pig. Changes in the physiological conditions of the cells cause alteration of the cell susceptibility to viruses.

To test the effect of cortisone upon tumour and viral growth in mice, mice were treated with 2·5 mgm. of cortisone at 4-day intervals after tumour grafting. In contrast with grafts in heterologous hosts (rats), the growth of the primary tumour in mice was suppressed by cortisone treatment. Moreover, in mice treated with cortisone, metastases were quite often found in lung and kidney (Fig. 2). Col.-*SK* virus was



(*a*) (*b*)

Fig. 2. Metastases in (*a*) lung and (*b*) kidney of mice treated with cortisone. (× 11)

injected into tumours in such mice and the *LD*50's of sarcomas in cortisone-treated and non-treated mice were compared. There were no significant differences in the virus titres. Therefore, differences in the virus titres between sarcomas grown in cortisone-treated rats and non-treated mice may not be due to the influences of cortisone but to the effects of the host animal.

Details of these experiments will be published elsewhere.

A Biological Action of Injected Deoxyribonucleic Acid

It is well known that when body cells are seriously injured, the blood and urine of animals are able to degrade deoxyribonucleic acid, in a way closely resembling the action of deoxyribonucleases I and II. In this communication we therefore refer to these activities as the effect of deoxyribonucleases. Several explanations of this phenomenon are possible. Two of them provided the background for this investigation : (*a*) the enzymes are extruded from damaged cells, (*b*) with the release of the cell contents a reaction is started which ultimately leads to a rise in deoxyribonuclease activity. The facts in favour of this point of view were given by Kowlessar and Altman[1]. They found rising deoxyribonuclease activities following irradiation of the whole body. In rats the maximum activity in the body fluids of deoxyribonuclease II is found on the first, and of deoxyribonuclease I on the sixth day, following exposure to X-rays. This makes it unlikely that one mechanism would be responsible for both maxima.

When cells are destroyed all kinds of substances may enter the body fluid pool ; for example, enzymes and the contents of the cell nucleus with its highly specific genetically active deoxyribonucleic acid. The body would have to neutralize this dangerous material and might bring an adaptive mechanism into action. If this were so, application of deoxyribonucleic acid should provoke a rise of deoxyribonuclease activity in the body.

We injected a solution of 0·2 per cent deoxyribonucleic acid in 0·85 per cent saline, *p*H 7·4, into the ear vein of rabbits ; the deoxyribonucleic acid was prepared from *Holothuria polii* sperm[2]. The injections were given during the course of a week, and a total of 78 mgm./kgm. was administered per rabbit. At zero time, after 1 day, 2 days and 5 days, blood samples were taken. The clotted blood was spun down at 5,000*g* (20 min.). 0·5 ml. of the serum, 0·5 ml. of a 0·01-*M* magnesium sulphate solution and 4·0 ml. of a 0·5 per cent deoxyribonucleic acid solution, all of *p*H 7·4–7·6, were brought to 25° C. and the viscosities were measured in an Ostwald-type viscometer with a water outflow time of 22·0 sec.

Table 1. Viscosimetric Determinations of Deoxyribonuclease Activities following Deoxyribonucleic Acid Injections

Incubation time (hr.)	Viscosity change in per cent (zero time viscosity 100)

19·5	+13·8±1·1			
22·5	+12·3±0·9			

Total : 630 measurements

The increments in viscosity and the incubation times are given in Table 1. Upon mixing deoxyribonucleic acid with zero-time serum there is an initial rise in viscosity. During the following 24 hr. the viscosity drops somewhat. In the sera withdrawn after injection the behaviour is different. In the initial phase the rise in viscosity is not very great, or is even negative, and during the next 24 hr. viscosity decreases considerably.

In the rabbit the natural deoxyribonuclease activities are quite low, but they are higher in the rat. It was therefore of interest to determine whether there is any deoxyribonuclease activation at all, since it is conceivable that the deoxyribonucleic acid molecule would be broken down by the high 'natural' deoxyribonuclease activity before it could develop its deoxyribonuclease-provoking effect.

Yet in the rat it was impossible to inject deoxyribonucleic acid solutions of as high a viscosity as was possible in the rabbit. It was therefore given intraperitoneally in doses of 500 mgm./kgm. This higher dose was thought necessary because of the different mode of application. For deoxyribonuclease determinations we used the method of Allfrey and Mirsky[3]. The acid and the neutral deoxyribonuclease were run in parallel. Five rats were killed one day after deoxyribonucleic acid application and another five one week later. A third set of untreated animals served as controls. The clear supernatant serum was used to act upon deoxyribonucleic acid for 0, 1 and 24 hr. at *p*H 5·2 and 7·4. Trichloracetic acid was then added and the solution centrifuged at 5,000*g* for

Table 2. Determination of Deoxyribonuclease Activities by the Method of Allfrey and Mirsky (ref. 3)

Time of incubation of samples (hr.)		Animals injected with saline		Animals injected with deoxyribonucleic acid solution	
		Deoxyribonuclease I	Deoxyribonuclease II	Deoxyribonuclease I	Deoxyribonuclease II
Rats	0	100	100	100	100

20 min. The clear supernatants served as substrate in the Dische reaction. In Table 2 the figures are given in percentage, zero time averages taken as 100.

The principal result of both series of investigations is the same. Injection of deoxyribonucleic acid provokes a sharp and highly significant rise in deoxyribonuclease activity. Apparently both deoxyribonucleases, acid and neutral, are activated. We believe that this behaviour might help in developing a biological test for deoxyribonucleic acid. We are aware of several further implications and investigations will be continued. A full account of the preliminary experiments will be given elsewhere.

We wish to thank the Deutsche Forschungsgemeinschaft for financial support. We are especially grateful to Dr. C. Vendrely and Dr. R. Vendrely from the Centre de Recherches sur les Macromolécules in Strasbourg, who, in a recent letter to us, stated that they had verified parts of our experiments.

Serological Detection of Fermentation Wastes

Waterborne wastes from the fermentation industries are difficult to differentiate from natural biological metabolites that occur in streams. Detection of characteristic antigens from organisms would serve to identify such wastes as contributors to the pollution of streams. A study was undertaken to determine if sufficient antigenic material for detection was produced in the medium during fermentation and if the antigens were sufficiently stable to permit recovery and identification in microgram amounts.

Three unrelated organisms, *Penicillium chrysogenum*, *Streptomyces lavendulae* and *Escherichia coli*, were grown in a non-antigenic medium consisting of glucose and inorganic salts using a fermentor stand variable drive assembly (New Brunswick Scientific Co., New Brunswick, New Jersey). The cultures were harvested during the vigorous growth stage when autolysis was at a minimum. The cells were removed from the broth with a millipore filter and filtrates autoclaved at 15 lb./in.^{2} for 15 min. The heated filtrates were vacuum concentrated at 56° C., dialysed against distilled water, and reconcentrated to a small volume. The concentrates were made isotonic before injecting into rabbits. Each animal received sixteen injections over a four-week period. While the concentrates from the *Penicillium* and *Streptomyces* were well tolerated, the *E. coli* concentrate was very toxic.

The antisera obtained from the rabbits seven days after the last injection were tested against their homologous antigens by the tube precipitin test. The concentrated filtrate from the submerged fermentation of *P. chrysogenum* failed to elicit any antibody response. Serum from rabbits receiving the *S. lavendulae* concentrate had a titre of 20 μgm. of antigen nitrogen/ml. The antiserum against *E. coli* concentrate had a titre of 1·25 μgm. nitrogen/ml.

The concentrates from *P. chrysogenum* and *S. lavendulae* were incorporated into Freund adjuvant ('Bacto-Adjuvant', Complete (Freund), Difco Laboratories) and injected into rabbits. The *Penicillium* antiserum, prepared this way, was precipitated with its homologous antigen at a dilution of 20 μgm. nitrogen/ml. The *Streptomyces* antiserum was capable of detecting 1·25 μgm. of nitrogen in the filtrate. Neither of these antisera cross-reacted with the opposite concentrate or the *E. coli* concentrate. No additional specificity reactions have been examined.

Antisera were also prepared against unheated saline-washed *P. chrysogenum*, *S. lavendulae* and *E. coli* whole cells. The *Penicillium* and *Streptomyces* mycelial antisera gave a precipitate with their homologous mycelia-free filtrates at a dilution containing 1·25 μgm. nitrogen/ml. The antiserum to the *E. coli* whole cells had an agglutination titre of 1 : 5,120 and gave a precipitate with 1·25 μgm. of filtrate nitrogen/ml.

The concentrates were studied by a slightly modified Ouchterlony[1] plate gel diffusion technique. There was a minimum of three antigens in the *E. coli* and *Penicillium* concentrate and at least five in the *Streptomyces* concentrate. The *E. coli* cell antiserum and the *E. coli* concentrate antiserum gave comparable patterns by the gel diffusion method when run against the *E. coli* concentrate.

The three concentrates were further purified by ethyl alcohol (70 per cent v/v) precipitation. The purified antigens from *Penicillium*, *E. coli* and *Streptomyces* reacted with their homologous cell antisera at dilutions containing 0·15, 0·075 and 0·15 μgm. nitrogen/ml. respectively.

The antigenic pattern of various *E. coli* cultures has been studied in detail by the agglutination test. Kauffmann[2] published a diagnostic scheme for the *E. coli* group based on the distribution of the *H*, *O*, and *K* antigens. This work has been extended by Ewing[3] until there are now 137 standard *O* group cultures and 77 standard *K* antigen strains. Several known serological types were fermented and processed as described previously. In general, the results of the precipitin test on the heated cell-free filtrates were correlated with the cell agglutination tests.

Four methods of recovering added antigenic material from Ohio River water were compared for their effectiveness. The methods were vacuum concentration, sodium sulphate precipitation, adsorption on aluminium hydroxide floc and concentration plus ethyl alcohol precipitation. Only the alcohol (70 per cent v/v) precipitation gave consistent results. The three alcohol-purified antigens could be detected individually or in combinations at a dilution of 3 μgm. antigen nitrogen per litre of Ohio River water. The tube precipitin assay was used because of its simplicity and reliability with multicomponent antigen – antibody reactions. The highly sensitive hæmagglutination inhibition or the complement fixation procedures were not investigated.

The stability, in Ohio River water, of antigenic material from fermentation filtrates was determined under laboratory conditions. While laboratory examination may not reveal the true susceptibility to biological destruction in a receiving stream, it does give an indication. The antigens from the *E. coli*, *Penicillium* and *Streptomyces* filtrates had a stability time of 4–6 days.

This work was performed under contract with the U.S. Army Chemical Corps, Fort Detrick, Frederick, Maryland.

Progesterone in the Blood of the Laying Hen

FRAPS *et al.*[1], using the bioassay method of Hooker and Forbes[2], reported progestational activity in the peripheral blood of the hen. Layne *et al.*[3], using chromatographic procedures, failed to find progesterone in chicken blood although they did identify this substance in extracts of ovarian tissue. In preliminary studies in this laboratory[4], chemical analysis failed to reveal progesterone in blood obtained by cardiac puncture, though the samples reacted positively to the Hooker–Forbes test.

Since progesterone is metabolized by the liver[5], and perhaps by other body tissues as well, a method was devised to minimize such loss. Samples were obtained from White Leghorn hens, six to fourteen months old, between 8.00 a.m. and 4.00 p.m. on the day following oviposition of the initial egg of a sequence. The adrenal glands were cauterized in birds under nembutal anæsthesia, and clamps were placed on the dorsal aorta posterior to the ovarian artery, on both common iliac veins just posterior to the caudal vena cava and on the vena cava anterior to the ovarian veins. The vena cava was opened distal to the last-mentioned clamp, and blood was drawn by suction during the period of 15–25 min. before heart action ceased; 20–35 ml. was obtained from each bird. These samples thus contained a large proportion of blood from the ovary prior to contact with the liver or any capillary bed.

Five samples, each containing 300 ml., were extracted with ethyl acetate by the method of Bush[6]; fat was removed by adding 70 per cent methanol, chilling overnight to − 10° C., and centrifuging at that temperature. The concentrated extracts were run on Whatman No. 2 chromatography paper, using *n*-heptane/methanol/water in the ratio of 5 : 4 : 1 at 38° C., after the method of Bush[6]. Authentic progesterone in this system had an R_F value of 0·73–0·76.

All extracts yielded fluorescent spots, each with the same R_F value as the authentic standard on the same paper. Two of these spots, treated with sodium hydroxide, developed the primrose-yellow fluorescence characteristic of an alpha-beta unsaturated ketone in ring *A*, and one spot, treated with 2,4-dintrophenylhydrazine[7], developed a visible light-yellow colour indistinguishable from that of a similarly treated authentic progesterone. The quantities of progesterone in these three spots, estimated by comparison with progesterone standards, were all more than 10 and less than 20 μgm.; thus, these extracts contained an average of 5 μgm. progesterone per 100 ml. blood. Two spots were eluted with ethyl acetate, and the residue taken up in sulphuric acid for absorption determination[8] at 300 mμ. The amounts determined by this method were, respectively, 4 and 5 μgm. per 100 ml.

Chemical identification of progesterone in these samples was doubtless made possible in large part by circumventing its loss in the peripheral tissues. Improved extraction techniques must also have been important, because earlier samples up to 150 ml. in amount, which were obtained in the same way but were less completely defatted, uniformly failed to yield detectable amounts of progesterone; yet these samples were positive to the Hooker–Forbes test. Application of these techniques to studies of diurnal variation of progesterone-levels in hen's blood will be reported elsewhere.

We are indebted to the National Research Council, Committee on Problems of Sex, for a grant in aid of research (*S*–11–57) that made this work possible.

Effect of Triiodothyronine on Radiosensitivity

REDUCTION in metabolic rate has been shown to reduce radiosensitivity, but the effect of an elevated metabolic rate has not been well established. Similarly, anoxia induced by various means reduces radiosensitivity. In recent years, the reverse of this phenomenon has been applied in the attempt to increase the radiation response. This is based on the assumption that the radiosensitivity of tissue is related to the degree of oxygen tension in a given tissue at the time of irradiation[1]. Data on the protective action of myxœdema are not extensive; the hyperthyroid state has been shown to hasten mortality in mice given acute lethal doses of total-body irradiation[2,3].

Thyroid hormone is known to produce an increase in the metabolic rate, increased oxygen consumption, flow of blood, and growth potential, demonstrated by enhanced mitotic activity. It was therefore postulated that such stimulation might also lead to an increase in the radiosensitivity of selected local tissues, both normal and neoplastic.

L-Triiodothyronine sodium, the potent fraction of the thyroid hormone that acts rapidly at the cellular level[4], was selected to induce the hyperthyroid state. (L-Triiodothyronine sodium was kindly supplied as 'Cytomel'-sodium by J. Clipson of Smith, Kline and French Research Laboratories.)

Two abnormal tissues were used: (1) a solid, non-metastasizing, non-systemic, myeloid chloroleukæmia rat tumour; (2) a mouse neuroblastoma of similar biological action. The latter tumour is so radio-resistant that it causes the mouse to succumb to the systemic effects of an exposure employed in the local irradiation of this tumour before sufficient time has elapsed for evaluation of tumour response. The rat chloroleukæmia was injected subcutaneously into the flanks of male Sprague–Dawley rats, weighing approximately 250 gm. Within two weeks after inoculation, this tumour attains a size of 2–3 cm. Administration of triiodothyronine was started at this stage; four consecutive doses of 200 μgm. each were given subcutaneously at 48-hr. intervals. Oxygen consumption before X-ray treatment increased 60–80 per cent above normal values. The hyperthyroid state was manifest clinically by excitement and irritability in this otherwise docile host. There was profuse water intake, diuresis and marked and rapid loss in weight despite striking voracity. The fur became rough and lost its sheen. The dosage of triiodothyronine given proved to be in excess of physiological tolerance as evidenced by the appreciable mortality among the animals, even before irradiation. In point of fact, it was observed that the induced hypermetabolic condition persisted for 5 days in the mice and about 10 days in the rats after discontinuation of the drug. The animals were irradiated 3 days after the last administration of triiodothyronine. They were not anæsthetized inasmuch as such treatment might cause changes in metabolic and respiratory rates. As a result, satisfactory immobilization of the exposed tumour-bearing portion of the rat, caged individually in a protective lead box, was not achieved with certainty in every case. Radiation was delivered at several dose-levels above and below the established tumoricidal dose (300–1,500 rads calculated at 1-cm. depth; 0·2-cm. copper H.V.L., 150 kV., 21-cm. F.S.D., 4-cm. cone). Immediately after X-irradiation, the rats were offered drinking water containing 0·05 per cent chloromycetin *ad libitum* in an effort to reduce the bacteræmia, severe diarrhœa, and death that occurs in animals exposed to the higher dosage-levels.

Only 103 of approximately four hundred animals survived long enough to permit adequate evaluation. Tumour response, judged by simple palpation of the treated site, was evaluated one week after X-ray treatment and weekly thereafter for eight weeks. Involution of the tumour until it was no longer palpable was found to occur within four weeks if treatment was adequate. Otherwise, there was a marked increase in size of tumour at this time. Elaborate histological observation transcended the scope of this initial project.

In the group of 52 euthyroid rats, the chloroleukæmia disappeared when a tumour dose of 1,000 plus or minus 200 rads was given. The same tumour, under the same conditions in 51 hyperthyroid rats, disappeared when a tumour dose of 500 plus or minus 200 rads was delivered. In neither group did this variation exceed 10 per cent of the total number of animals treated. The few exceptions in each group that were not cured, even by the largest doses employed, may be attributed to inadequate immobilization during X-irradiation.

When sufficient experimental results had been obtained to support the thesis that increased radiosensitivity resulted from induction of a hyperthyroid state, two patients were selected for such treatment. Both had histologically verified squamous cell bronchogenic carcinoma with widespread metastases. Several sizeable tumour masses protruding from the soft tissue were selected as sites for trial treatment. The patients' basal metabolic rate was raised markedly (above 40 per cent) by triiodothyronine, given orally (400–600 μgm. daily), and was maintained at that level throughout the period of radiotherapy. Regression of tumour masses was unequivocal at one-third the dose-level (1,500 rads) at which such a response might ordinarily be expected. Treatment was suspended at half of the customary therapeutic level (3,000 rads), because the tumour mass could no longer be palpated. The overlying skin also demonstrated an inordinately early and severe radiation response (wet reaction), indicating that the skin reaction was enhanced to a degree.

One patient has been followed for three months, and in this short observation period there has been no recurrence of tumour in the treated sites. During this interval, however, he has had additional metastases in similar sites elsewhere on the body which were irradiated with an identical dose without the benefit of triiodothyronine-induced hypermetabolism. Irradiation alone had little effect on these subcutaneous tumour metastates when the patient was not in a hypermetabolic state.

Whether the profound response that was seen in these hyperthyroid animals and patients reflects only a quantitative change has not yet been determined. It is believed that inasmuch as a basically radioresistant tumour like bronchogenic carcinoma cannot ordinarily be eradicated even by large exposures, there may well have been a fundamental, biological, qualitative change in these neoplastic cells induced by the thyroid hormone triiodothyronine. A series of classically non-radiosensitive human tumours, such as gastrointestinal carcinomas, brain tumours, and connective tissue tumours, is now being subjected to similar investigations, which will contribute to the clarification of this radiobiological response.

The research was conducted at the Argonne Cancer Research Hospital, U.S. Atomic Energy Commission, University of Chicago, and was supported in part by the Chicago Tumor Institute. We are indebted to E. Simmons, L. O. Jacobson and E. T. Morch for assistance and valuable suggestions. We are also grateful to J. W. J. Carpender for his interest and for referring the clinical cases.

Effect of DDT on Egg-laying by *Oscinella frit* L.

OATS sprayed with DDT soon after emergence largely escape frit fly tiller attack, even on small plots growing within an untreated field. It was not known how DDT confers this protection. Preliminary observations during 1955–56 showed that there were far fewer eggs present on the sprayed than on the

unsprayed plots. This was confirmed in replicated trials during 1957–58. The results are given in Table 1.

On all dates but one there were significantly more eggs on the controls than on the DDT plots ($P = 0{\cdot}05$ or $P = 0{\cdot}01$), the average difference being of the order of 75 per cent. It seemed unlikely that this was due to DDT killing the flies quickly and so resulting in far fewer flies on DDT plots, because the plots were small and flies were coming in from outside. A measure of the actual number of flies present was obtained by coating some plants on each plot with a sticky material and recording the flies caught. During May 13–27, 237 flies were caught on 295 plants on DDT plots and 279 flies were caught on 305 plants on the control plots, indicating that the numbers of flies on the treated and untreated plots were substantially similar.

That the reduction in egg laying must have been due to a very local effect was shown as follows. On May 22, eggs were counted on the outer rows of sprayed plots and on the second row of the adjoining control plots so that the sampled rows were about 14 in. apart. There were 1·55 and 0·16 eggs per plant on the untreated and treated rows ($P = 0{\cdot}01$) and eggs were found on 55 and 16 per cent of the plants respectively.

Next, tests were carried out to observe the behaviour of the flies when given the choice of untreated surfaces and surfaces treated with DDT. Batches of 10 females were placed in metal cylinders 8 in. in diameter closed at one end by two joined semicircles of Whatman No. 1 filter paper, one of which had been sprayed either with 0·2 per cent DDT miscible or with 0·2 per cent DDT emulsion and thoroughly dried. Every half minute during 5 min. flies were counted on each semicircle and each test was repeated four times: in all, 135 flies were counted on DDT miscible, 167 on DDT emulsion paper and 191 and 177 flies on the respective untreated semicircles. The differences were not large or consistent and it seemed improbable that, in the field, DDT deterred the flies from alighting or that they had a marked preference for the untreated plants.

Kennedy[1] has found that contact with DDT shortens resting periods of mosquitoes and it is known that excitation generally follows contact with DDT. We tested the behaviour of frit flies by placing batches of 10 females in cylinders closed at one end by a filter paper, either unsprayed or sprayed with 0·2 per cent DDT. Every half or every full minute we counted the flies actually on the papers, those remaining stationary, and the number of flights made in a 15-sec. period.

The results were as follows:

(1) For the first 8 min. there were slightly fewer stationary flies on DDT papers than on the controls: on the average 1·8 and 2·7 respectively. The position was then reversed, the difference increasing with time until by the forty-fifth minute there were 8·0 stationary flies on DDT and 1·5 on the controls.

(2) During the first 6 min. there were 3·7 flights in 15 sec. on DDT and 1·8 on controls. The position was then reversed and there was a continuous reduction of flights on DDT down to 0·5 after 30 min. compared with 5·6 on controls. The results for DDT in the first 8 min. showed wide variations and they require confirmation. However, the gradual reduction of movement after 10 min. on DDT papers was a constant and well-defined feature of all the tests. After 20–30 min. most of the flies remained in one place for several minutes, the only activity being that of cleaning. Paralysis of one or two individuals and lack of response to light were also noted after about 30 min.

Waterhouse and Scott[2] found that DDT prevented the laying of eggs by the sheep blow-fly. The number of flies landing appeared to be similar but there was less searching for oviposition sites on the treated sheep. They concluded: "protection is conferred by an inhibition of one of the early stages in the chain of reflexes leading to oviposition". This probably applies equally well to frit fly, although 'contact repellency' may play some part. Where comparatively large numbers of eggs had been found on treated plots (for example, site *A* in 1958, Table 1) there was afterwards much less damage than expected, suggesting that DDT also acts by killing the newly hatched larvæ.

A Simple Autoradiographic Method for distinguishing Insects labelled with Phosphorus-32 and Sulphur-35

The use of radioactive tracers for labelling insects is finding many applications in field studies on dispersion and survival. In particular, the introduction of autoradiography for detecting tagged insects[1] has presented entomologists working in remote areas with a simple and practical tool. In

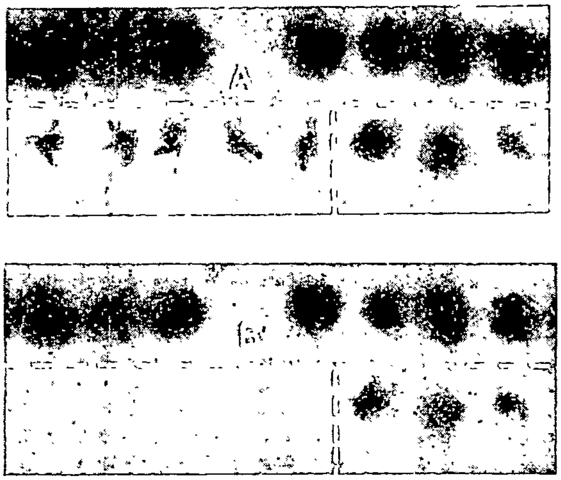

Fig. 1. Autoradiographs of labelled *Anopheles gambiae* after application of the film in two layers; showing, *A*, the first layer of film, in direct contact with the mosquitoes, and, *B*, the second layer. The three divisions in each strip of film represent mosquitoes labelled as follows: upper row, males and females treated with phosphorus-32 at 5 μc./l.: lower row, left, males labelled with sulphur-35 at 20 μc./l.; lower row, right, females with phosphorus-32 at 3·5 μc./l.

studying the longevity of marked populations, however, this technique suffers from the disadvantage that it records only the presence or absence of radioactivity in recaptured insects. No variation in the marking of different releases is possible, and a second release can only be made when all the survivors of the first have disappeared. When the numbers released depend upon the scale of laboratory rearing, as in the case of insects such as *Anopheles gambiae*, this may appreciably retard the accumulation of results. To surmount this difficulty the following method, that enables the separation by autoradiography of insects labelled with one of two or possibly more different isotopes, has been devised.

The method is based on differences in the energy of the radiation emitted by different radioisotopes. Phosphorus-32, the most widely used in entomological research, emits beta-particles with the relatively high energy of 1·71 MeV. It gives excellent autoradiographs. Sulphur-35, which has been used for studies on Lepidoptera[2], emits beta-rays with no more than 0·167 MeV. It gives very sharp images of labelled objects; but its penetrating power is extremely low. Mosquitoes marked with either of these isotopes are readily separated by exposure on strips of X-ray film laid in two superimposed layers. After an appropriate exposure time, blackening of the layer of film in immediate contact with the labelled insects occurs in both cases; but with sulphur-35 the first layer acts as an effective absorber, and prevents any detectable quantity of radiation reaching the second layer. Insects labelled with phosphorus-32 give good autoradiographs through at least four layers of film, while those with sulphur-35 leave an image on the first layer only (Fig. 1).

Sulphur-35, in addition to phosphorus-32, is being used for field studies on *A. gambiae* at concentrations of 10–15 μc./l. (100–150 mμc. per larva) in the breeding pans. Recaptured mosquitoes are laid out for testing on strips of cellulose tape, which are afterwards applied directly to single strips of industrial X-ray film. After an exposure time of one to two nights (16–40 hr.) the films are developed. It is usually possible to distinguish insects labelled with sulphur-35 from those with phosphorus-32 by the sharpness or otherwise of the image. But in every doubtful case confirmation is obtained by re-exposing the same strip of mosquitoes, using this time two layers of film.

The weakness of the images produced by sulphur-35 is offset by the relatively long half-life of 87·1 days. This means that loss of radioactivity through decay is probably slight during the life-time of most tropical mosquitoes. But in the case of phosphorus-32, labelled insects surviving beyond six weeks may be difficult to detect. If recaptures beyond this age are not likely to be encountered, a combination of the two isotopes in the same insects might distinguish them from those labelled with one only. In double-labelled insects, the phosphorus-32 present at the time of capture tends to mask the presence of the sulphur-35; but if all marked recaptures were set aside until the former had decayed sufficiently, say after two or three months, and were then re-tested, the sulphur-35 would still show up. By some such method the separation of three overlapping releases might become possible.

I am indebted to the staff of the Isotope School at the Atomic Energy Research Establishment, Harwell, for encouragement and for providing facilities during the early stages of this work; and to Prof. D. S. Bertram of the London School of Hygiene and Tropical Medicine for supplying me with eggs of *Aedes aegypti* used in the initial experiments.

Cytochromes in Chloroplasts

IT has been concluded from experiments with barley leaves that chloroplasts contain cytochromes f and b_6 and no cytochrome c[1]. We have been able to extend the observations to two other widely differing species and to record certain characteristics of the cytochromes present.

The chloroplasts were obtained from laminæ of *Caulerpa prolifera* growing in the Bay of Naples and from leaves of *Vicia faba* from the adjacent district. They were separated and purified by the method of James and Das[2], which secures a total separation from accompanying mitochondria, etc. Suspensions of the chloroplasts in a mixture of 40 per cent sucrose-phosphate buffer medium[2] with 60 per cent glycerol were examined in 1-cm. cuvettes in a Beckman *DU* spectrophotometer with photomultiplier attachment.

Suspensions were examined as freshly extracted, after reduction with a pinch of dithionite and after decolorization with cold acetone at − 10° C.

The redox difference spectrum of decolorized bean (and also spinach) chloroplasts showed the three absorption maxima to be expected from the presence of a single cytochrome. The magnitudes of the peaks, $\gamma \gg \alpha > \beta$, had also the relations to be expected and the positions were within the usual ranges and were taken to lie as follows: α at 563–564 mμ, β at 526–528 mμ, γ at 430 mμ. Since the cytochrome was 'insoluble' and not denatured by the rapid treatment with cold acetone, it is assumed to be the cytochrome b_6 observed by Hill in barley. The absorption curves of acetone-extracted chloroplasts from *Caulerpa prolifera* were considerably distorted by interfering substances, but peaks were again observable at 562–564 mμ and 430 mμ.

The redox difference spectra of pure suspensions of living chloroplasts showed similar α and γ peaks, and also additional peaks at 556 and 422 mμ suggesting the presence of cytochrome *f* in the undamaged chloroplasts, though in smaller amounts than cytochrome b_6. Similar results were obtained with both *Caulerpa* and *Vicia*.

It was found that if the pure chloroplast suspensions from *Caulerpa prolifera* were illuminated strongly the difference spectrum between illuminated and unilluminated developed peaks in both the visual and Soret regions. After five minutes the peaks in the cytochrome *f* positions (α and γ) were the more conspicuous, but after 20 min. the peaks in the cytochrome b_6 positions were the higher. Bean chloroplasts similarly illuminated also showed similar increases of absorption, but there was a rapid return to the original condition when the light was removed. Rapid reoxidation might be expected of cytochrome b_6, which is readily autoxidizable.

Positions of the α peaks in the visual region corresponded closely in the green and decolorized preparations for both cytochromes; but in the Soret region there were definite divergences. The observed position of the γ bands with the green suspensions was always about 5 mμ higher than with the decolorized material. The position of the γ band of cytochrome *f* in the decolorized bean material was at 422 mμ, which corresponds well with the value 421 mμ given by Davenport and Hill[3] for extracted cytochrome *f*. It is presumed that the apparent shift of the peak in the green chloroplasts is due to interfering pigments removed by the acetone.

According to our observations the positions of the absorption maxima are as follows:

Cytochrome	*f*		b_6		
Absorption band	γ	α	γ	β	α
Caulerpa prolifera	423*	555	430	—	563
Vicia faba	422	556	430	528	564

* Adjusted value from observation of 428 mμ with green chloroplasts.

Cytochrome *c* was never found in chloroplast suspensions freed from any accompanying mitochondria, but a very small contamination sufficed to make the characteristic α band visible at 550 mμ.

Further details of these observations are being published in the *Pubblicazione della Stazione Zoologica di Napoli.*

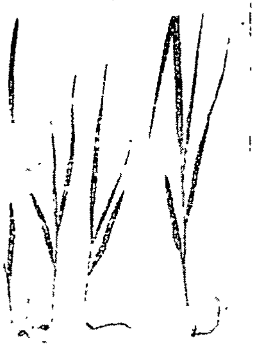
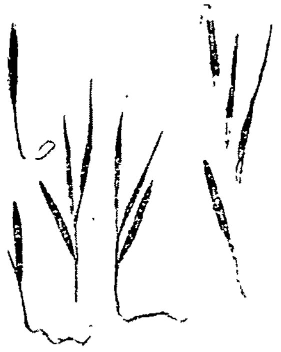
Translocation of ^{14}C-labelled 2,4-Dichlorophenoxyacetic Acid in Barley and Oats

The 'hormone' herbicides 2-methyl-4-chlorophenoxyacetic acid (MCPA) and 2,4-dichlorophenoxyacetic cid (2,4-D) have repeatedly been shown to produce deformities in the straw and spikes of cereal plants when applied before five or six leaves have developed. This connexion between deformation and age of plants as led to the assumption that floral and vegetative primordia are particularly sensitive to compounds with hormone activity but become more resistant with progressing development. Experiments with 2,4-D labelled with carbon-14 in the carboxyl group, however, suggest that this is scarcely likely to be the true explanation.



1



2

Fig. 1. Barley plants, 1–4 leaf stage
Fig. 2. Radioautograph of the plants in Fig. 1

Seedlings of barley and oats were given applications of 10 μl. of a 0·5 per cent solution of labelled 2,4-D (total activity, 0·3 μc.) at the centre of the upper surface of each leaf. The plants were treated at six stages: 1, 2, 3, 4, 5 and 6 leaves; the total dose of 2,4-D applied was thus 10 μl. multiplied by the number of leaves. This corresponds to field practice where plants with 5 or 6 leaves receive and take up very nearly 5 or 6 times as much 2,4-D as those with a single leaf.

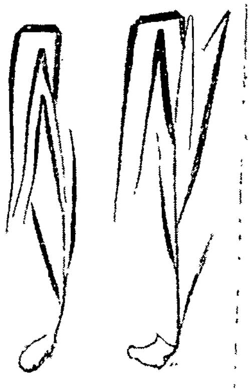
After application, which occurred in the morning, the plants were left 4–8 hr. in a greenhouse with artificial illumination. The plants' roots were then rinsed of soil, the area of application was covered with adhesive paper, and the plants were placed between several layers of warm blotting paper in a high-glazing photographic press, where they were killed by heating to 60° C. for 15 min.

Immediately afterwards the plants were mounted with rubber cement on white cartons and pressed to paper thinness in a specially constructed press. (A freeze-drying unit as recommended by Crafts[1] for desiccation of plants was not available.) After desiccation and pressing for about a week the plants were placed on X-ray films for radioautography; the period of exposure was three weeks.

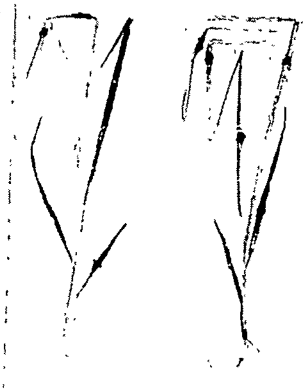
Barley plants in the stages of one, two and three leaves are seen in Fig. 1 and the corresponding radioautographs in Fig. 2. The radioactive 2,4-D is in these young plants effectively translocated from the point of application to the stem and through the stem to the roots, thus passing through the floral and vegetative primordia.

Figs. 3 and 4 show barley plants in the 5–6 leaf stage and the corresponding radioautographs. At this stage of development translocation is slight and does not extend to the stem and roots as it does in younger plants.

Oats, in contrast to barley, show little translocation in the early stages (1–2 leaves); 2,4-D is not transferred to the hypocotyle, the seed and the roots to such an extent as in barley, and will thus come in contact with the embryonic primordia to a smaller extent. Translocation in oat plants becomes effective in the 3–4 leaf stage when 2,4-D is detected in all parts of the plants. Later, in the 5–6 leaf stage,



3



4

Fig. 3. Barley plants, in 5–6 leaf stage
Fig. 4. Radioautograph of the plants in Fig. 3

translocation again becomes slight and the active compound remains largely in the leaves, as in barley.

Histological detection of labelled 2,4-D in floral primordia of plants at different stages of development was attempted in exploratory experiments (Petersen *et al.*, unpublished). These attempts, however, were unsuccessful.

In order to test whether floral primordia in older plants are susceptible to 2,4-D, barley and oat plants were given syringe injections of a single drop of 0·5 per cent 2,4-D solution in the leaf sheath immediately above the floral primordium. The plants responded very strongly with formation of tubers near the soil surface and twisting and cracking of the stems in several places ; the floral primordium was mostly strongly deformed or altogether destroyed, even in plants older than the 5–6 leaf stage.

The reason why cereals do not develop deformed spikes or stems on treatment with 2,4-D after the 5–6 leaf stage may thus be the lack of translocation and not necessarily an increasing degree of resistance in the vegetative and floral primordia.

Similar experiments with wheat and rye are in progress.

I am greatly indebted to Prof. A. S. Crafts and to Dr. H. Levi for instruction in their technique of tracer studies.

Effect of Rust Infection on Oxidative Phosphorylation of Wheat Leaves

WE have already reported[1,2] that the rate of consumption of oxygen by wheat leaves infected with stem rust fungus is not augmented by treatment with 2,4-dinitrophenol, in contrast with the great respiratory increase observed in healthy leaf tissue after treatment with dinitrophenol.

This observation is strikingly related to the well-established fact that the consumption of oxygen by leaf tissues infected with rust is also significantly increased, and that the glycolysis and further respiratory pathways linked with stimulated glycolysis play an important part in the respiratory metabolism of diseased but not of healthy wheat[2]. There is an analogy between the physiological effects of infection with rust and those of treatment with dinitrophenol Therefore, on the basis of the results obtained i seemed reasonable to suppose that the ineffectivenes of dinitrophenol in the case of tissues infected wit rust is due to the fact that the pathological respirator mechanism has already undergone alterations simila to those which occur in healthy leaves as a resul of treatment with dinitrophenol[3].

It is widely accepted that 2,4-dinitrophenol exert its stimulatory effect on biological oxidation an especially on glycolysis by interfering with th normal phosphorus metabolism. It has been demonstrated that treatment with dinitrophenol resulted i increased adenosine triphosphatase activity, in consequence of which a higher level of P-acceptor (adenosine diphosphate) is available. This allows a greate rate of breakdown of sugar and an enhanced uptak of oxygen[4]. To gain a deeper insight into the mechanism of respiratory increase due to infection with rus fungus and to dinitrophenol, comparative analyse for phosphate fractions of healthy and affected leave were made.

Wheat plants (Hungarian rust-susceptible variet *R*23) were grown under ordinary greenhouse conditions. The primary leaves were inoculated with a suspension of stem rust (*Puccinia graminis*, race 21 uredospores. On the fourteenth day after infectio leaves were collected from both healthy and disease plants and assayed for phosphate by a modificatio of the Lowry–Lopez method[5]. 2,4-Dinitrophenol i a concentration of 10^{-4} *M* was absorbed into the lea tissues.

Table 1 shows that the amount of the phosphat fraction labile to acid decreased significantly i plants infected with rust as compared with health ones. The amount of phosphate labile to acid in th phosphate fraction soluble in acid, and free fro nucleoproteins, phospholipids and phosphoprotein also decreased. (In the experimental conditions use phosphate labile to acid represents the inorgani phosphate released principally from adenosine tri and di-phosphate.) A slight but definite statisticall significant increase was also demonstrated in th amount of inorganic phosphate fraction. These results strongly suggest that infection results i destruction of adenosine triphosphate.

In uninfected leaves, following absorption c 2,4-dinitrophenol (Table 2), the amount of acid-labil phosphate decreased, as in the case of rust infectio but to a greater extent. A concomitant increase o inorganic phosphate was also observed.

In the cases of treatment with dinitrophenol an of rust infection, as compared with water-infiltrate and uninfected healthy plants respectively, a diminution of total organic phosphate and of the organi phosphate of the fraction soluble in acid occurred

Table 1. PHOSPHATE FRACTIONS OF HEALTHY AND RUST-INFECTE WHEAT LEAVES
(Mean values of five experiments in three series)

Fraction	μgm. Phosphate/100 mgm. fresh weight: Healthy	Diseased
Total phosphate	105·4	97·4
Inorganic phosphate	65·5	70·2
Organic phosphate	39·9	27·2
Acid-labile phosphate*	15·4	3·5
Acid-labile phosphate* of the acid-soluble fraction	14·7	3·5
Organic phosphate of the acid-soluble fraction	16·8	9·8

* Increase of inorganic phosphate after hydrolysis with *N* hydr chloric acid at 100° C. for 7 min.

Table 2. EFFECT OF WATER AND DINITROPHENOL ON PHOSPHATE FRACTIONS OF HEALTHY WHEAT LEAVES
(Mean values of five experiments in three series)

Fraction	gm. Phosphate/100 mgm. fresh weight: 24 hr. after water infiltration	gm. Phosphate/100 mgm. fresh weight: 24 hr. after dinitrophenol infiltration (10^{-4} *M*)
Total phosphate	65·6	59·8
Inorganic phosphate	36·0	56·2
Organic phosphate	29·6	3·6
Acid-labile phosphate*	8·8	0·4

* Increase of inorganic phosphate after hydrolysis with *N* hydrochloric acid at 100° C. for 7 min.

These results clearly show that an anabolic alteration of metabolism connected with rust infection, namely, a synthesis of organic phosphate and an incidental activation of a system by which the energy of adenosine triphosphate is utilized, and a simultaneous decrease in the phosphate fraction labile to acid cannot occur. Although an increase in the nitrogenous fraction insoluble in acid (such as protein) has been observed after infection, this phenomenon is explained by the spread of fungal body in the leaf tissues. At the same time, we found no increase but, on the contrary, a decrease of organic phosphate fraction. Destruction of acid-labile phosphate and organic phosphate in diseased plants reaches such a high level that it predominates over the synthesis of organic phosphate arising incidentally from the growth of fungal body. There seems to be no necessity, therefore, for postulating that the synthetic reactions of fungal metabolism utilize the energy of adenosine triphosphate and thus accelerate the reaction:

$$\text{ATP} \rightarrow \text{ADP} + \text{P}_i \qquad (1)$$

The experimental results rather support the view that the infection (by a toxic action) inhibits the rate of oxidative phosphorylation just as in the case of treatment with dinitrophenol. In both cases oxidative phosphorylation is uncoupled from respiration and this gives rise to a greater amount of phosphate acceptor (adenosine diphosphate) and inorganic phosphate. These compounds govern the reactions controlling the rate of glycolysis and of the whole process of respiration, as pointed out by Krebs[6].

This rate-controlling function of inorganic phosphate and adenosine triphosphate explains the effect of rust infection. The destruction of acid-labile phosphate (first of all adenosine triphosphate) and the simultaneous increase of inorganic phosphate by acceleration of reaction (1) create a high level of both phosphate acceptor and of inorganic phosphate in the diseased tissues, and the availability of these two compounds gives rise to a pathologically high rate of respiration.

Occurrence and Metabolism of Oligosaccharides in the Broad Bean (*Vicia faba*)

PAPER chromatographic analysis of aqueous methanolic (75 per cent v/v) extracts of dormant broad bean seeds using (*A*) ethyl acetate/acetic acid/formic acid/water (9·0 : 1·5 : 0·5 : 2·0 v/v) and (*B*) ethyl acetate/pyridine/water (10 : 4 : 3 v/v) as solvents with *p*-anisidine hydrochloride as spray reagent[1] showed that both the embryos and cotyledons contained small amounts of raffinose, glucose and fructose together with relatively high concentrations of sucrose and higher molecular weight oligosaccharides. Traces of xylose were also detected (cf. Kawamura, Tsuboi and Nakamura[2]). The testa contained only glucose and fructose.

A large-scale extract of whole beans was concentrated to a syrup and fractionated on a carbon–'Celite' column[3]. The oligosaccharides present were identified as: sucrose [m.p. 178° C. (anhydrous), $[\alpha]_D^{20} + 64{\cdot}3$ (conc. 2·8), octaacetate m.p. and mixed m.p. 84–85° C.]; raffinose [m.p. 117–120° C. (anhydrous), $[\alpha]_D^{20} + 123{\cdot}5$ (conc. 1·1)]; stachyose [$[\alpha]_D^{20} + 145°$ (conc. 1·5, anhydrous), consumed 7·0 moles of periodate per mole] and verbascose [infra-red spectrum identical with that of authentic verbascose; consumed 8·8 moles of periodate per mole]. The identity of the oligosaccharides was further proved by a comparison of their electrophoretic (0·2 *M* borate buffer, *p*H 10) and chromatographic behaviour (in solvents *A* and *B*) with that of authentic specimens, and also by a study of the hydrolysis products obtained with sulphuric acid (0·5 *N*) and yeast invertase. Electrophoretic and chromatographic evidence for the presence of a tetragalactosylsucrose in the extract was also obtained.

Germination of the beans on moist filter paper (25° C.) resulted in a rapid disappearance of the higher oligosaccharides from all parts of the seeds, leaving sucrose and an increased concentration of glucose and fructose.

The carbohydrase activity of embryos and cotyledons from both dormant and germinated (5 days) beans was examined. The tissues were macerated with cold acetate buffer (0·2 *M*; *p*H 5·6) and, after centrifugation, the solutions dialysed against buffer at 5° C. The ability of these preparations to hydrolyse sucrose, raffinose (producing free galactose) and maltose (at 35° C. under toluene using 5 per cent w/v substrate concentrations) was taken as an indication of the presence of sucrase, α-galactosidase and maltase, respectively, in the tissues. The digests, together with suitable controls, were examined on paper chromatograms after 48 hr. (Table 1).

Attempts to obtain an active sucrase preparation from dormant embryos by extraction with buffers of varying *p*H (4·5, 5·6 (0·2 *M* acetate) and 6·4 (0·1 *M* phosphate)) containing L-cysteine (10^{-3} *M*) were unsuccessful. Sucrase rapidly appeared, however, in excised embryos which were allowed to rest on moist filter paper (25° C.). Quantitative measurements of sucrase activity in germinated embryo

Table 1

Carbohydrase	Dormant		Germinated	
	Embryo	Cotyledon	Embryo	Cotyledon
Sucrase	–	–	+++	–
α-Galactosidase	+	+	++	+
Maltase	+	+	+	+

preparations, using the Somogyi reagent[4], showed that the addition of a dormant embryo extract had no inhibitory effect. It would appear, therefore, that sucrase is synthesized in the embryonic tissues in the early stages of germination, and it is probably not present in a latent form in the dormant tissues. Hora[5] has also demonstrated sucrase formation in germinating barley. Germinated embryo preparations (pH 5·6; 35° C.; 48 hr.) degraded stachyose and verbascose with the liberation of galactose, glucose and fructose in both cases. With dormant cotyledon preparations under the same conditions, however, the only free monosaccharide liberated was galactose.

During these studies it was observed that the sucrase in germinated embryos was strongly inhibited (at 10^{-3} M concentrations) by mercuric chloride and phenylmercuric acetate and to a lesser extent by iodoacetic acid. An aqueous extract of the bean testas also behaved as an inhibitor.

The role of sucrase in the plant is not understood. In the case of the germinating bean seed the increase in reducing substances together with the appearance of sucrase activity may be significant. The rapid disappearance of galactose-containing oligosaccharides from the germinating tissues and the absence of significant quantities of free galactose suggest that the former compounds may form an important sugar reserve for the developing plant.

A full report of this work will be given in a later publication.

I wish to thank Prof. E. L. Hirst for helpful discussions, Prof. E. J. Bourne for valuable suggestions and Prof. J. E. Courtois for a specimen of verbascose.

Inhibition of Sulphate Reduction in Paddy Soils

THE hydrogen sulphide formed in waterlogged soils is a serious problem in rice cultivation. It inhibits the uptake of water and nutrients, and may even cause root-rot[2-6]. The disease due to these injurious effects (browning disease, 'brusone', brand, aki-ochi, etc.) in unfavourable weather conditions, chiefly too little sun (1949, 1954 and 1955), caused considerable damage in Hungary. Injury appeared mainly after stem elongation, when the oxygen supply to the roots is greatly reduced[1].

My previous experiments for controlling the injuries showed that results can best be obtained not by binding the hydrogen sulphide, but by preventing its formation. It is formed mainly by reduction of sulphate, for which the cellulose–butyric acid fermentation provides the hydrogen source[5,6].

To eliminate the hydrogen required for the reduction, experiments were carried out in the laboratory and in the field. 1·5 gm. cotton was placed between wet rice soil-disks in containers after soaking in 30–80 mgm. per cent ammonium and sodium sulphates or in 30–50 mgm. per cent ammonium or potassium nitrate. 14 days after waterlogging and incubation 8·8–26·0 mgm. sulphide per container was formed in the controls and in the containers with sulphates. No sulphide was found in the containers with nitrates.

The atomic hydrogen, formed by butyric acid fermentation, is used to reduce nitrate, and, consequently, cannot be utilized by the sulphate-reducing bacteria as a source of energy.

Experiments in the field also yielded positive results: for this purpose ammonium nitrate mixed with powdered lime ('Péti só') proved to be the most suitable.

An Aphid-transmitted Tobacco Ring-Spot-like Virus isolated from *Begonia tuberhybrida*

Begonia semperflorens was reported as a host plant for tobacco ring-spot virus by Price[1], but no record of natural infection of begonia with this virus is known.

A plant of *Begonia tuberhybrida* multiflora with leaves showing yellow spots surrounded by a necrotic line was tested for virus infection. The symptoms on tobacco plants, variety Samsun, and cucumbers, variety Blanc hâtif, inoculated with sap were similar to the symptoms described by several workers for plants infected with viruses of the tobacco ring-spot group.

The inactivation temperature in tobacco sap after 10 min. heating was about 70° C.

The virus was easily transmitted by *Myzus persicae* from tobacco to cucumber (1–2 min. acquisition feeding after 2–3 hr. starvation; 24 hr. inoculation feeding; 10 aphids a plant).

Tobacco ring-spot viruses are not usually transmitted by aphids. McWorther[2] reported that a virus of this group isolated from leguminous plants was transmitted by aphids, but only in company with pea enation mosaic virus. Smith and Brierley[3] reported transmission by aphids of tobacco ring-spot virus from gladiolus to gladiolus, but in conditions that did not completely secure the absence of bean yellow mosaic virus, which is prevalent in this plant.

Our results confirm that viruses of the tobacco ring-spot group can be transmitted by aphids; in our conditions, bean yellow mosaic virus was not present in combination, and the absence of cucumber mosaic virus was secured by a cross-protection test.

The virus isolated from *Begonia* did not protect tobacco plants against infection by the type strain of tobacco ring-spot virus.

Thanks are due to Prof. R. Vanderwalle for criticism of this work and to Dr. K. M. Smith for material infected with virus.

Chitin in Pogonophora

POGONOPHORA secrete and inhabit tough, horny tubes. Recently, Hyman[1] quoted unpublished results indicating that the tubes of Pogonophora were composed of cellulose. In view of the presumed phylogenetic relationship of Pogonophora with lower chordates this might have been expected, since the tunicate test is rich in cellulose (tunicin). However, on examining three species of *Siboglinum* (*S. atlanticum* Southward and Southward, *S. inermis* Southward and Southward[2], and *S. caulleryi* Ivanov) kindly given to us by Dr. A. J. Southward, we found the tubes to be lacking cellulose, but rich in chitin. Later, through the kindness of Academician Ivanov, we were given specimens of the tubes of *Zenkevitchiana longissima* Ivanov[3], and the same conclusion about their composition was reached.

Tubes of the four species available withstood treatment for 20 min. in saturated aqueous potassium hydroxide at 150° C. The alkali-treated tubes, after washing, were coloured brown by iodine in potassium iodide solution, becoming violet when this was replaced by dilute sulphuric acid[4]. Alkali-treated tubes were soluble in mineral and acetic acids. Both cellulose and chitin are relatively stable in alkali, under the conditions specified; but the above colour reactions, and solubility in acids, are properties shown only by chitin[5]. The tubes resisted solution in Schweitzer's cuprammonium reagent, in which cellulose dissolves; and the same result was obtained if tubes were pretreated in strong alkali (as above) or in a solution of chlorine dioxide in acetic acid ('diaphanol').

Chitin, being considered as a polymer of 2-acetamido-2-deoxy-α-D-glucopyranose (N-acetyl-D-glucosamine), on acid hydrolysis yields D-glucosamine; and, on enzymic degradation, N-acetyl-D-glucosamine[6]. The pogonophoran tubes showed these reactions.

Tubes of the four species were hydrolysed in sealed vessels with 6 *N* hydrochloric acid at 100° C. for 6 hr. After drying the hydrolysate over phosphorus pentoxide and potassium hydroxide, the residue was taken up in water and run on partition paper chromatograms against D-glucose and D-glucosamine hydrochloride, using eight different solvent mixtures. The chromatograms were sprayed with aniline hydrogen phthalate, silver nitrate, or the Elson and Morgan reagents. A substance (evidently an amino-sugar) behaving like glucosamine (or galactosamine) was present in large amounts; but no glucose was detectable. On conversion to the corresponding pentose by Stoffyn and Jeanloz[7] procedure *B*, the acid hydrolysate of *S. atlanticum* yielded arabinose, confirming the presence of glucosamine (as opposed to galactosamine).

Tubes of *S. atlanticum* were prepared for enzymic hydrolysis by heating with 4 *N* aqueous potassium hydroxide at 100° C. for 3 hr. (to remove the substances other than chitin mentioned below), and the residual chitin was dispersed by brief treatment in 12 *N* hydrochloric acid; after washing, the suspension was incubated at 37° C. with an enzyme preparation from the puff ball *Lycoperdon pyriforme*[5], buffered at *p*H 5·0, having chitinase and cellulase activity. Samples taken after 18, 42 and 66 hr. were concentrated *in vacuo* and chromatographed in butanol/ethanol/water (4 : 1 : 5). N-acetyl-glucosamine was shown to be present with the Elson and Morgan reagent, and no glucose was detectable with aniline hydrogen phthalate.

Proteins invariably accompany chitin, and a number of amino-acids were found in the acid hydrolysate of the tubes. These amino-acids must have been derived from a very stable protein in so far as it withstands environmental dissolution; but it is not yet known whether stabilization is derived from disulphide links (being a keratin), or quinonoid links (being a sclerotin).

Production of Experimental Scurvy in a Bird Species

IT has been generally supposed that all species of animals except the primates and the guinea pig are able to synthesize ascorbic acid according to their requirements. In a previous communication[1], using our technique of incubating liver and kidney tissues of different species of animals with D-glucuronolactone as substrate in presence of cyanide, it was shown that in some species the kidney could effect the synthesis and in some the liver. In the evolutionary ascent the mechanism for the synthesis of ascorbic acid appeared to pass from the kidney to the liver and then to disappear altogether. It was also unexpectedly observed that neither the liver nor the kidney tissue of the red-vented bulbul (*Pycnonotus cafer*, Linn.) and of the Indian fruit-bat (*Pteropus medius*) could effect the synthesis. Thus at least one avian species, the red-vented bulbul, and one mammalian species, the Indian fruit-bat, were apparently incapable of synthesizing ascorbic acid. It was suggested, therefore, that the cyanide technique might offer a simple means for determining the capacity of different species for the synthesis of ascorbic acid. This supposition has now been proved to be correct by actually placing some red-vented bulbuls on a scorbutic diet and producing in them ascorbic acid deficiency symptoms, which could be cured by ascorbic acid.

Nine red-vented bulbuls were put on a diet of parched gram powder for a fortnight to get them used to the diet. Then they were placed on the scorbutic diet composed as follows: 80 parts of parched gram powder (autoclaved as an aqueous paste at 18 lb. per sq. in. pressure for 45 min.), 12 parts of casein, 5 parts of yeast powder, 1 part of Steenbock's salt mixture No. 40 and 2 parts of cod-liver oil. The average weight of the birds fell gradually from 35 gm. to 28 gm. in 15 days and they all showed deficiency symptoms. These were loss of feathers and particularly the tail, drooping of the head, sluggishness and peevishness. On the sixteenth and seventeenth days, two birds dropped steeply in weight and died. Then three birds, which were in the worst condition, were given a daily supplement of 3 mgm. of pure ascorbic acid dissolved in 0·1 c.c. water by mouth and the four remaining birds were allowed to continue on the scorbutic diet only. All the three birds which received the ascorbic acid supplement began to gain weight and after 10–12 days of feeding the supplement the feathers and the tail began to grow, the birds became brighter in appearance and sat on perches and were obviously getting well. The four birds which were left on the scorbutic diet only became worse and died one after another on various dates in the course of 45 days.

At autopsy the scorbutic birds showed subcutaneous hæmorrhage, hæmorrhage inside joints, particularly knee joints, and in the liver.

In order to find whether, as a contrast to the red-vented bulbul, another avian species, the bank-myna (*Acridotheres ginginianus*, Latham), which was shown by the cyanide technique to be capable of synthesizing ascorbic acid, would be independent of an exogenous supply of ascorbic acid, two birds of this species were placed on the scorbutic diet, and they have continued to be healthy for a period of 72 days.

Our thanks are due to the Indian Council of Medical Research for a research grant.

A Soil Fungus Trap

THE screened immersion-plate method[1-3] for isolating soil fungi has the disadvantages that the plates are not very simple to make and are not suitable for use in stony ground. In addition, when a pit is dug or a cut is made for insertion of plates, the gas relations of the soil are disturbed and some drying of the exposed surface occurs, and these factors may influence the growth of fungi. A development of the screened immersion plate which appears to show promise in overcoming these disadvantages is described here. Essentially the method involves the removal of a soil core and its replacement by a tubular version of the screened immersion plate within one piece of apparatus. The apparatus consists of a stainless steel rod which fits quite closely into a stainless steel tube. Water agar is contained in a number of holes bored through the rod which oppose the same number of holes bored in the tube. A metal stop on the rod fits into two slots in the tube and ensures alignment of the two sets of holes. The lengths of rod and tube employed, and the arrangement of the metal stop and of the holes are such that, when assembled, the section of rod with the agar-filled holes occupies only half the length of the tube. When the unoccupied half of the tube is pushed into soil a core or plug is cut. When the tube is pushed farther, the core and the soil ahead are compressed farther, and the cored space is then occupied by the section of the tube containing the rod. This enables exposure of the agar to a soil surface, through the apertures in the tube, in much the same manner as in screened immersion plates. The soil surface thus exposed has been little disturbed, and isolation of those fungi capable of growing from soil on to the agar can readily be effected. The compression of the soil involved in the removal of the core occurs beyond the area of soil to be sampled and will have little effect on the growth of fungi.

The method used in recent experiments is described briefly as follows. Rod and tube, unassembled, were placed in a large test-tube and sterilized by dry heat (160° C. for 1 hr.). After cooling, sterile water agar was dispensed into the holes in the rod with a hypodermic syringe under aseptic conditions. The rod was inserted into the tube with the agar-filled holes turned away from the apertures in the tube, and carried into the field in a plugged, sterile test-tube. A small hole was dug and the trap pushed horizontally into the soil profile at the required level with the tube apertures lowermost. The rod was then turned so that the stop fitted the slots and thus brought the holes filled with agar opposite the apertures in the tube. The soil dug out was replaced and the trap left for four to seven days depending on the growing season. Before digging up, the rod was rotated to turn the holes filled with agar away from the apertures in the tube and then the trap was removed bodily and placed in a sterile container. In the laboratory the agar plugs were punched out of the rod on to a nutrient medium in Petri dishes and incubated for further study.

The dimensions of the rod and tube now employed are:

Tube (prepared from 22 gauge stainless-steel tube, outside diameter $\frac{5}{16}$ in.) 4 in. long, with three apertures, $\frac{3}{32}$ in. in diameter, centres $\frac{1}{2}$ in. apart, bored in the first 2 in. of the tube, the distal aperture centre being $\frac{1}{4}$ in. from the centre of the length of the tube.

Rod (prepared from stainless-steel rod, diameter $\frac{1}{4}$ in.) $3\frac{1}{2}$ in. long, with three holes, $\frac{3}{32}$ in. in diameter, bored through it, the first hole centre $\frac{1}{4}$ in. from one end of the rod, the metal stop, made by pushing an $\frac{1}{8}$-in. diameter stainless steel wire through a hole in the rod, 2 in. from the same end of the rod.

The edge of the tube which is pushed into the soil is suitably bevelled on the inside to provide a good cutting edge. The trap is pushed into the soil by pressing on the exposed end of the rod with a small wooden handle, the thrust being imparted to the tube by the metal stop. The metal about the apertures was lightly filed to prevent packing of soil in the apertures when the trap is pushed into the ground.

In experiments in soil under perennial ryegrass a number of fungi have been isolated which included *Fusarium culmorum*, *Cylindrocarpon radicicola*, *Rhizoctonia* sp., *Mortierella* spp., and a number of non sporing forms, all of which had been isolated also b screened immersion plates from the same soil.

I wish to acknowledge the helpful discussions I ha with Dr. R. D. Northey and Dr. K. Strzemienski i the development of this technique.

Royal Aeronautical Society (at the Institution of Civil Engineers, Great George Street, London, S.W.1), at 6 p.m.—Mr. H. G. Conway: "Drone Aircraft".

Institute of Metal Finishing (at Northampton Polytechnic, St. John Street, London, E.C.1), at 6.15 p.m.—Mr. J. P. Dewar: "Trends in Polishing".

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 8.30 p.m.—Colonel G. R. Laclavere: "Antarctica and the I.G.Y.".

Tuesday, December 16

Royal Society of Arts, Commonwealth Section (at John Adam Street, Adelphi, London, W.C.2), at 5.15 p.m.—Dr. L. Dudley Stamp: "Land Utilization in the Commonwealth".

Institution of Electrical Engineers, Measurement and Control Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on "Modern Control Techniques on the Railways" opened by Mr. W. J. Webb and Mr. L. A. Ginger.

Plastics Institute, London and District Section (at the Wellcome Building, 183–193 Euston Road, London, N.W.1), at 6.30 p.m.—Mr. V. H. Wentworth: "Plastics in the Construction of Buildings".

Tuesday, December 16—Wednesday, December 17

Powder Metallurgy Joint Group of the Iron and Steel Institute and the Institute of Metals (at Church House, Great Smith Street, London, S.W.1)—Symposium on "The Powder Metallurgy of Ceramic-Metal Materials".

Wednesday, December 17

University of London (at the Postgraduate Medical School of London, Ducane Road, London, W.12), at 2 p.m.—Dr. J. M. Barnes: "Experimental Study of Toxic Substances".*

Royal Meteorological Society (at 49 Cromwell Road, London, S.W.7), at 5 p.m.—Mr. R. C. Rainey: "Some Observations on Flying Locusts and Atmospheric Turbulence in Eastern Africa"; Mr. C. G. Johnson: "Vertical Distribution of Aphids in the Air and the Temperature Lapse Rate".

Institute of Fuel (at the Institution of Civil Engineers, Great George Street, London, S.W.1), at 5.30 p.m.—Short papers on "The Work of the Boiler Availability Committee" presented by Mr. F. W. Lawton, Mr. H. E. Crossley, Mr. D. C. Gunn, Mr. W. F. Harlow, Mr. J. R. Jenkinson and Mr. W. G. Marskell.*

Institution of Chemical Engineers (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Mr. J. W. Mullin: "Liquid Distribution in Grid Packings. Part 1: The Mechanism of Liquid Spread". Part 2: "Evaluation of Packing Constants".

Society of Chemical Industry, Food Group—Nutrition Panel at 14 Belgrave Square, London, S.W.1), at 6.15 p.m.—Dr. J. P. Masterton and Mr. T. C. Gallant: "Nutritional Problems in Polar Regions, Part 2".

British Institution of Radio Engineers, London Section (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6.30 p.m.—Mr. I. J. P. James: "A Vidicon Camera for Industrial Colour Television".

Oil and Colour Chemists' Association, London Section (at the Royal Society of Tropical Medicine and Hygiene, 26 Portland Place, London, W.1), at 7 p.m.—Mr. F. E. Warner: "Common Problems and Chemical Engineering".

Thursday, December 18

Society of Chemical Industry, Road and Building Materials Group (at 14 Belgrave Square, London, S.W.1), at 2.30 p.m. and 5.30 p.m.—Scientific Papers.

Institution of Mining and Metallurgy (at the Geological Society of London, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Dr. Hulbert Marchandise: "Adsorption Kinetics Applied to Flotation"; Dr. H. N. Rhoden: "Structure and Economic Mineralization of the Silvermines District, County Tipperary, Eire".

London Mathematical Society (at the Royal Astronomical Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Prof. L. C. Young: "Some Geometrical Inequalities".

Royal Statistical Society (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.15 p.m.—Mr. J. C. R. Dow and Mr. L. A. Dicks-Mireaux: "A Study of Wage Inflation in the U.K. 1946–56".

Royal Aeronautical Society (at the Institution of Mechanical Engineers, Birdcage Walk, London, S.W.1), at 6 p.m.—Mr. E. W. Pike: "The Traffic Control Over the North Atlantic".

Friday, December 19

Society of Chemical Industry, Corrosion Group (at 14 Belgrave Square, London, S.W.1), at 2.30 p.m. and 5.30 p.m.—Meeting on "Modern Views of Fundamental Electrochemical Processes". Mr. E. C. Potter: "Cathodic Processes"; Mr. T. P. Hoar: "Anodic Processes".

Institute of Navigation (at the Royal Geographical Society, 1 Kensington Gore, London, S.W.7), at 5.15 p.m.—Captain G. S. Ritchie, D.S.C., R.N., and Captain A. J. R. Tyrell: "The Admiralty Chart".

Institution of Mechanical Engineers (at 1 Birdcage Walk, London, S.W.1), at 6 p.m.—Mr. P. Daniel: "The Hydraulic Turbine in Evolution" (James Clayton Lecture).

Friday, December 19—Saturday, December 20

Linnean Society of London (at Burlington House, Piccadilly, London, W.1), at 10.30 a.m. daily—Symposium on "Experimental Approaches to the Problems of Growth and Form in Plants".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Ecologist (man, with a first- or second-class honours degree and preferably some knowledge of statistics), to join a team studying marine plankton using continuous plankton recorders—The Officer-in-Charge, Oceanographic Laboratory, Scottish Marine Biological Association, 78 Craighall Road, Edinburgh 6 (December 20).

Microbiologist (with a good honours degree in botany or agricultural botany) at the Welsh Plant Breeding Station, for work associated with the breeding of new strains of clover—The Registrar, University College of Wales, Aberystwyth (December 20).

Senior Scientific Officer (with a science degree of a university of the United Kingdom with passes in biochemistry, zoology, botany, etc., and preferably five years experience in serology in the Health Service basic grade of Scientific Officer) at the Blood Transfusion Centre, Oxford—The Director, Regional Blood Transfusion Centre, Churchill Hospital, Headington, Oxford (December 20).

Scientific Assistant (with a biological degree, the ability to write correct English and preferably some knowledge of foreign languages), for work which includes the abstracting and reviewing of biological literature—The Director, Commonwealth Bureau of Plant Breeding and Genetics, School of Agriculture, Cambridge (December 31).

Senior Lecturer in Mathematics at the University of Natal, Pietermaritzburg—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (South Africa, December 31).

Professor of Agricultural Botany—The Secretary and Registrar, University College of North Wales, Bangor, North Wales (January 1).

Applied Mathematician (with a university honours degree in applied mathematics or in physics, chemistry or a branch of engineering with evidence of suitable attainment in applied mathematics, preferably in hydrodynamics or aerodynamics) in the Chemical Engineering Section, Chemical Research Laboratories, C.S.I.R.O., Fishermen's Bend, Melbourne, initially to collaborate with an experimental team investigating the formation of boundary layers in two-phase fluid systems—The Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting Appointment No. 590/689 (January 3).

Grade II Lecturer (with a genuine interest in inorganic chemistry, preferably on the preparative side and possibly with radiochemical experience) in Inorganic Chemistry—The Registrar, The University, Bristol (January 10).

Chair of Psychology in the University of Cape Town, South Africa—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (South Africa, January 15).

Lecturer in Pure Mathematics—The Secretary, The Queen's University, Belfast (January 15).

Chair of Medicine tenable at the Royal Free Hospital School of Medicine—The Academic Registrar, University of London, Senate House, London, W.C.1 (January 19).

Senior Lecturer in Mechanical Engineering—The Registrar, The University, Sheffield (January 31).

Senior Lecturer or Lecturer (Physiologist, with special interests in either general or cellular physiology) in Zoology at the University of Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, January 31).

Plant Physiologist (with a good honours degree) at the Unit of Experimental Agronomy, Agricultural Research Council, Oxford, to work on fundamental aspects of phytotoxicity and the mechanisms of the actions of herbicides—The Secretary, Agricultural Research Council, Cunard Building, 15 Regent Street, London, S.W.1 (February 1).

University Demonstrator in Bacteriology—Dr. G. P. Gladstone, Sir William Dunn School of Pathology, The University, South Parks Road, Oxford (April 1).

Agricultural Education Officer (with a university degree, considerable experience in tropical agriculture and teaching ability) in the Department of Agriculture's Training Centre, British Honduras, to take charge of, and to teach, the fundamental principles of agriculture to trainees—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.63/31/09.

Analytical Chemists (with at least H.N.C. or good "A" levels in G.C.E.) at U.K.A.E.A. Research Group Establishments at Harwell (Berks) and at Winfrith (Dorset), to undertake environmental field surveys and the radio-chemical analysis (for specific radioisotopes) of biological materials and, possibly, to investigate the application to this work of instrumental techniques, for example, gamma spectrometry—The Group Recruitment Officer (1264/34), Atomic Energy Research Establishment, Harwell, Berks.

ENGINEER (with at least three years practical experience and experience in one of the following fields: electromechanical design or estimating and contract work), to be concerned with all phases of the design, construction and operation of a 200-MeV. Heavy Ion Linear Accelerator—Prof. S. Devons, Department of Physics, The University, Manchester.

LECTURER (graduate, preferably with teaching, industrial and/or research experience) IN CHEMISTRY at the Mid-Cheshire College of Further Education, Hartford, Northwich, for at least one branch of chemistry to H.N.C. or higher level—The Director of Education, County Hall, Chester.

PHYSICAL CHEMIST (with at least two years experience in post-graduate research or in industry), to assist with teaching of applied chemistry to students of chemical engineering and to conduct research in applied physical chemistry—Dr. R. F. Strickland-Constable, Imperial College of Science and Technology, London, S.W.7.

RESEARCH ASSISTANT (with a sound knowledge of electronics and an interest in radio propagation problems) IN THE DEPARTMENT OF PHYSICS, for work in radio observation of artificial satellites—The Registrar, University College of Wales, Aberystwyth.

Photography at work

helping to ensure the purity of metals

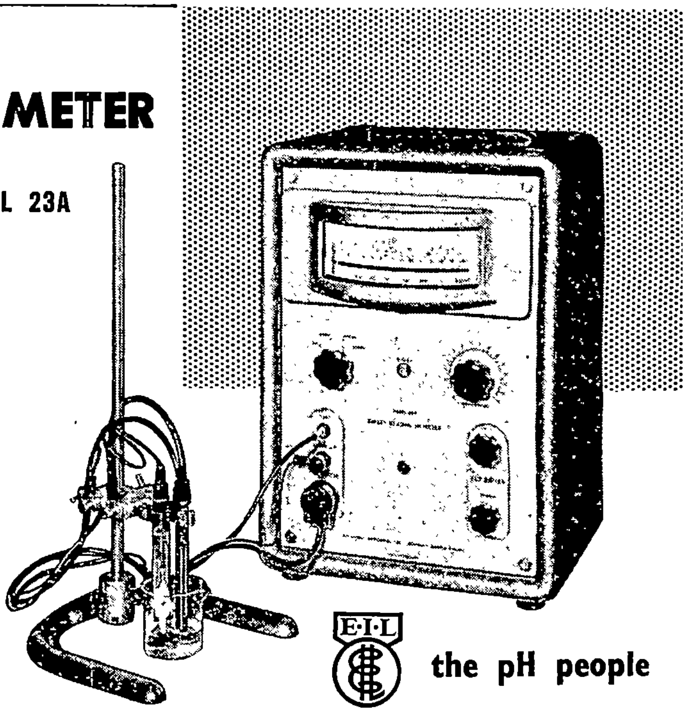
Constant checks on the purity of all metal supplies delivered to the Aluminium Wire & Cable Company help to ensure that the finished products will meet the most exacting electrical and mechanical requirements. These checks are made rapidly and accurately by spectrographic analysis. The Company writes:

"For the high degree of accuracy required in the micro-photometric determinations of trace elements, it is essential that the photographic plates used should be uniformly coated with a fine-grade emulsion having a 'straight-line' characteristic curve and providing a high contrast, especially in the ultra-violet region of the spectrum.

"We use Kodak B.10 rapid-processing spectrographic plates exclusively for this work."

B.10 Kodak High-Contrast Rapid-Processing Plate

Kodak Limited, Industrial Sales Division, Kodak House, Kingsway, London, W.C.2.



DIRECT READING pH METER

MODEL 23A

This high-grade laboratory pH Meter is one of the most widely used instruments in electrochemical research.

Some 50 different types of electrodes are available for pH, redox and micro analytical work. Stable to 0.02 pH with a B.S. precision grade meter and a recorder output.

Certificate of intrinsic safety No. I.S.3032

E·I·L the pH people

MUTUAL ASSISTANCE BETWEEN COMMONWEALTH COUNTRIES

THE Commonwealth Trade and Economic Conference which met in Montreal during September 15–26 is of interest to scientists and technologists on several counts, not all of which are apparent from the brief report of the Conference which has been issued as a White Paper*. Telecommunications, though specialized, is a subject of obvious interest, and here the Conference agreed, in principle, on the basis of a recent report by the Commonwealth Telecommunications Board, that a round-the-world Commonwealth coaxial-cable telephone system should be constructed. If laid link-by-link the whole enterprise would probably take some ten years to complete, and might cost £88 million. Many technical problems remained to be solved, however, and apart from the financial questions still to be discussed, the Conference made no attempt to reach detailed or binding commitments.

This new enterprise, which has recently become technically possible, is expected, like earlier systems of communication, to strengthen Commonwealth associations and promote Commonwealth trade, and thus illustrates the way in which technology and science can assist the economic advance of peoples, in this case, the members of the British Commonwealth of Nations. That is notably true of research, and it is surprising that the report makes no mention of the announcement at Montreal by the United Kingdom Government that it is considering a proposal to establish, under the general control of a committee of the Privy Council, an Overseas Research Council, which would be concerned with research, particularly in the Commonwealth (*Nature* of November 22, p. 1413). In referring to this announcement, in a speech at Abingdon on October 20, the Lord President of the Council said that our existing organizations in industrial, medical and agricultural science would be made available to give assistance through the medium of this new body; this is an indication of the importance which the Government attaches to international research and follows on a powerful plea recently made by Mr. R. E. Casey, the Australian Minister for External Affairs (*Nature* of November 22, p. 1397), and further details will be awaited with interest.

At first sight it would appear that some care must be taken to avoid duplicating the work which is already being done through the Colonial Research Council, the Colonial Products Council, the Colonial Medical Research Committee, the Committee for Colonial Agricultural, Animal Health and Forestry Research and other bodies. The new body will obviously have a wider scope, so it may be presumed that before it begins to function a sufficiently clear indication will be given of its proposed relations to these bodies, so that informed criticism can be brought to bear before and not after duplication or waste of effort has occurred. It should be a prime purpose of any new organization to improve the means of communication so as to ensure that the most effective use is made of existing resources and information, and to avoid any diversion of the Commonwealth's severely limited resources of scientific and technical man-power into unproductive occupations.

It is obvious from the report that one purpose of the Montreal Conference in adopting these proposals is to enable the more prosperous members of the Commonwealth to contribute more effectively to the rapid advance of the less-developed countries. It is apparent from the latest report of the Consultative Committee of the Colombo Plan (p. 1718 of this issue) that there is increasingly general recognition that this is a matter for close collaboration between all Commonwealth countries and that the benefits are not all one way. The report emphasizes that it is of the utmost importance that the less-developed countries of the Commonwealth should succeed in implementing their development programmes, and the Conference agreed that, even to the extent of some sacrifice, all that is possible must be done to assist in the solution of these vital problems.

This problem of development, including technical assistance, is discussed at some length in a section of the report devoted to development, although in other sections also some measures intended to assist development, directly and indirectly, are indicated. The Conference recognized the importance of a broad joint effort on the part of Commonwealth countries to enable economic development to proceed as rapidly as possible in its under-developed countries, and it is seriously considered whether such development would be assisted by setting up a new institution such as a Commonwealth Development Bank. Methods of mobilizing resources for Commonwealth development are to be studied further; and meanwhile, although it was agreed that the present flexible and informal machinery for consultation is working well and is well-fitted to the character of the Commonwealth relationship, it was decided to co-ordinate these existing arrangements under the name of a Commonwealth Economic Consultative Committee. An offer by the United Kingdom Government to provide a Commonwealth House, to be available for the constituent bodies of the Council and for other Commonwealth meetings, was welcomed.

Possibly of even greater interest to the scientist than the announcement of the establishment of an Overseas Research Council, and certainly of equal importance, is the agreement of the Conference both to establish a new scheme of Commonwealth scholarships and fellowships, and to convene a meeting early in 1959 to work out details of the new scheme, and also to consider what might be done to expand and improve mutual assistance between Commonwealth countries. Even from the point of view of technical assistance, the section on education is one of the most interesting and important in the report; but it is no less vital in regard to the problem of expansion and utilization of the Commonwealth's resources of trained man-power, upon which economic advance and indeed scarcity and prosperity depend in the United Kingdom and also elsewhere.

---

* Report of the Commonwealth Trade and Economic Conference. Pp. 17. (Cmnd. 539.) (London: H.M. Stationery Office, 1958.) 1s. net.

This view found wide support in the debate in the House of Lords on November 4 in reply to the Queen's speech. Baroness Elliot of Harwood, quoting the reference in that speech to the increasing association of peoples with the management of their own affairs, urged that education is fundamental, and is no less essential to the successful working of free democracy than to enable Britain to play a leading part in the twentieth-century world. Lord Soulbury, in particular, elaborated the theme, referring to the magnitude of the task of educating the multitudes of newly enfranchised electors in the countries which have become independent in the past decade, so that they should have some capacity for discrimination and criticism. Although social services such as education are the responsibility of these new independent governments themselves, the older countries could help by providing money, as through the Colonial Development and Welfare Fund, which up to last year had provided £36 million for this purpose, but still more by providing teachers.

All delegations at the Conference were agreed on the great importance of education and training as an indispensable condition of development, and the Commonwealth countries were manifestly resolved to help one another as much as possible in this field at all levels. In some countries, as Lord Soulbury indicated, the most pressing need at present is for primary education, for more teachers and for help in training them. Accelerated programmes to train foremen and technicians are also needed, as well as for new technical and other training institutions. Many of the universities in the Commonwealth would benefit from having the services for a few years of teachers from older institutions, and from being able to send to them some of the younger members of their staffs to serve temporarily as teachers. Apart from its educational value, this greater mobility and interchange would be of considerable value in the communication of ideas and the stimulation of research, and an increase in the number of scholarships and fellowships for tenure abroad and open to both undergraduate and postgraduate students would also help in that way, and in maintaining high standards of advanced study.

Much is already being done in this respect, apart from such special programmes as the Colombo Plan. More than 50,000 overseas students are already receiving instruction in Commonwealth countries—most of them from other Commonwealth countries—while there is a substantial flow of teachers and experts within the Commonwealth, and a large expansion in these facilities was already in prospect when the Conference met. The decision in principle to establish a new scheme of Commonwealth scholarships and fellowships was taken with the view of meeting the ever-increasing need for people equipped with general training to serve in all the varied processes of a complex society. Some of the new scholarships will be in the field of the humanities and the social sciences as well as the natural sciences, and will be designed to recognize and promote high standards of intellectual achievement, and others may be at various levels in the teaching field.

Within a few years of its inception, the programme is expected to cover some thousand scholars and fellows, of which the United Kingdom undertook to be responsible for one-half and Canada for one-quarter, while the Australian delegation has meanwhile announced an increase of 150 in the number of places made available for trainees under the technical co-operation programme of the Colombo Plan. The exact scope and detailed arrangements of the whole programme will be worked out after consultation with university and other educational authorities in Commonwealth countries at a meeting to be held in the United Kingdom early in 1959. The composition of this meeting remains to be determined. The meeting will also be asked to review existing arrangements for co-operation between Commonwealth countries in the field of education and to make recommendations for any improvement or expansion that may be possible, particularly in regard to the supply and training of teachers.

In welcoming the announcement of this new fellowship and scholarship scheme, Baroness Elliot hoped that it would be possible to make such scholarships available to all types of boys and girls and not only to those who might go to university and school staffs. She suggested that some exchanges might be made on the lines of those arranged very successfully by the National Federation of Young Farmers' Clubs and by the English Speaking Union. Lord Soulbury commented on the need to ensure that those seconded for educational service abroad should be assisted to obtain suitable posts on their return to Britain, and should not find that their professional prospects had suffered; and he referred also to the importance of the technician, in agriculture as well as in industry, and the bearing of elementary education on the effective use of the technical expert.

These are all particular facets or details of the whole problem, to which no doubt due attention will be given by the conference when it meets; and it may well be found that there is enough continuing work for it to develop, as Lord Soulbury suggested, into a permanent Commonwealth Council of Education, replacing the Imperial Education Committee which lapsed about 1930. Existing arrangements for educational interchange have grown up over a long period of years, and while there may be real advantages in their being in many hands, it may be useful to have some permanent co-ordinating or advisory body even if no adjustments are necessary to make the existing arrangements correspond more closely to present needs. The broad subject has already engaged the attention of the Home Universities Conference, which in December 1957 discussed the subject of academic mobility at some length.

The proposed conference should certainly consider this in the slightly wider context of professional mobility in general. From what was said at the Home Universities' Conference in 1957, it seems likely that overseas representatives will ensure that due attention is given to some of the points, such as pensions schemes, where government action should be a decisive factor in removing some of the existing obstacles to mobility. That, of course, is one matter in which the British Government representatives should be ready to concert action; but in the meantime it is to be hoped that Dr. B. V. Bowden's plea for serious study of the technical aspects of the problem is receiving attention. Indeed, one of the most important tasks to be attempted before the conference meets is to ensure that the question of scholarships and fellowships is put in its proper perspective in relation to the training and supply of men and women of high ability, and the way in which their services can be most effectively used throughout the Commonwealth.

Attention to such factors as conditions of service may help to ease one aspect that has caused some concern in Britain, apart from putting such careers in a truer perspective. The third report of the Migration Board, to which the Earl of Albemarle directed attention in the House of Lords on November 20, has referred to an increased loss of skilled and professional workers, in terms of absolute numbers, with the upward trend of emigration, as the broad conclusions drawn from the Board's study of the statistics for 1956, while the dominating feature of United Kingdom emigration in 1957 was the exceptionally heavy flow to Canada. The Board, however, did not find any cause for present concern, and in a written reply to a question in the House of Commons on November 4, the Minister of Labour, Mr. Ian Macleod, claimed that the Civil Service Commission had reported that recruitment of British scientists in the United States and Canada for research fellowships had shown encouraging results.

Nevertheless, Sir John Cockcroft, speaking in Manchester on that day, expressed the fear that too many of the best of Britain's young scientists and future leaders would be attracted overseas by the better facilities and salaries which would result from the present expansion of basic scientific research. Sir John was pleading in this connexion for the more liberal endowment of university research with equipment and assistance. He suggested, in particular, that an increase of even 1 per cent in expenditure on research and development in this direction would pay handsome dividends and greatly help to maintain our position in the world.

However, it is not simply the aspect of salaries and the actual level of scholarships and fellowships that needs to be considered if the new scheme is to have its full effect. The availability of equipment for research and teaching, the ancillary facilities, whether technicians or even clerical staff, the provision of adequate library facilities, and questions of publication and conditions of service are all important; they bear no less on the efficient use of our limited resources of trained man-power than they do on its mobility, and on our capacity to ensure that the flow is in both directions, with all that is implied in this not merely for Britain but also for the whole Commonwealth. It was rightly said in the debates in Parliament that the new scheme represents a great challenge. It is a challenge not merely to teachers and educational authorities of the Commonwealth but also—perhaps especially—to scientists and technologists of the Commonwealth, to see that the issues raised are considered imaginatively and constructively. Full use must be made of an unrivalled opportunity to remove some of the existing obstacles to the utilization of scientific work and to promote an interchange of people and thought which will prove increasingly fruitful.

NUMERICAL METHODS IN FUNCTION-SPACE

The Hypercircle in Mathematical Physics

A Method for the Approximate Solution of Boundary Value Problems. By Prof. J. L. Synge. Pp. xii+424. (Cambridge: At the University Press, 1957.) 70*s*. net.

PROF. SYNGE'S well-produced book provides a fascinating description of methods which he, with Prof. Prager, evolved to solve certain boundary value problems. It begins with a description of the geometry of function-space, and the claim that no specialized mathematical knowledge is required of the reader is for once true. The account of the properties of function-space theory in the first half of the book is not only clear and easy to read but also possesses an attractive style which makes the book difficult to put down once one has started to read it. What may well be fresh and unusual concepts to many readers are introduced so naturally, in small doses, that initial apprehensions are soon forgotten and one becomes eager only for more.

To find the solution to a boundary value problem requires the determination of the unique function which is common to the set of all functions satisfying the governing differential equation and to the set satisfying the boundary conditions; in the language of function-space, we have to find the unique point of intersection of two linear subspaces of infinite dimensionality. It is easy to build up within each of these subspaces constituent parts which are of finite dimensionality. These parts are themselves subspaces, which in general cannot be expected to intersect, but the common perpendicular of which is readily defined. It is proved that the unique point of intersection of the subspaces of infinite dimensionality lies on the hypercircle (the intersection of a hypersphere with a hyperplane) for which the shortest distance between the subspaces of finite dimensionality is a diameter. If the radius of the hypercircle is small then its centre is an approximation to the required point of intersection. Certain inequalities are also proved relating to the Dirichlet integral (that is, in the torsion problem, to the torsional rigidity).

Prof. Synge illustrates the methods particularly by reference to the torsion problem. The theory of function-space is his means to attain the end of solving this and other problems within a known degree of approximation. His description of the means is so delightful that it is disappointing to find the numerical results in the end not so satisfying. The set of algebraic equations which has to be solved to determine the shortest distance between the subspaces of finite dimensionality, in the solution of a torsion problem, are closely similar to the set which is presented in the standard method using finite-difference approximations; but the values of the stress function which these equations yield, in the torsion of a hollow square (Fig. 4.58*a*), are suspect in that even their second differences are sufficient to show a marked lack of smoothness. Furthermore, the numerical assessment of the torsional rigidity, although placed between bounds, is, on the evidence also of results for the torsion of a hollow square, no better than, if indeed as good as, that derived from the simplest finite-difference approximations.

The book is stimulating, and valuable in that it offers a novel approach to the numerical solution of boundary value problems; one looks forward to further developments of its methods.

D. N. de G. Allen

SHIPS IN ROUGH WATERS

Ships in Rough Water

By J. L. Kent. (Nelson's Nautical Series.) Pp. xiv+287. (London: Thomas Nelson and Sons, Ltd., 1958.) 32*s*. 6*d*. net.

AFTER devoting the whole of his professional career to the study of the performance of ships, Mr. J. L. Kent has written a book on a subject in which he is exceptionally well qualified. During his many years' experience of testing model ships, and research at the National Physical Laboratory, Mr. Kent not only attended numerous ship-trials under generally favourable conditions but also made ocean voyages on ships of various types with the express purpose of studying their behaviour in the varied and difficult conditions in which they normally operate.

This book is based on these experiences. It also contains a survey of theory and practice relating to the movement of sea and ships. There are three parts dealing respectively with ocean weather; behaviour of ships in a seaway; and resistance and propulsion of ships in rough water. Each part contains numerous references to relevant papers which have appeared over many years and the technical discussion is well illustrated. It is evident that the author has thoroughly searched the literature on his subject. The sub-division of the text is excellent. It is difficult to find any aspect of the performance of ships at sea which is not discussed, yet each is dealt with compactly so that the book is not unduly long. The outcome is a volume which is sufficiently technical to be of value to the owner, the designer and the student of ships, while it is written in language which is simple, direct and lucid so that it may be enjoyed by all who have a knowledge of and a love for the sea and ships.

The author is revealed as a person of exceptional powers of observation and acute memory for detail. Wherever possible he gives suggested explanations fo phenomena observed which appear to require explaining. The critical reader may not always find himself i agreement with the explanations offered, but will b impressed by the exhaustive treatment and the ver real effort to apply the knowledge gained to th improvement of the design of ships in relation to thei behaviour at sea. The final chapter is devoted t summarizing the author's conclusions, and is noteworthy for its conciseness.

In recent years the attention of the tank experimenter has been given more and more to the investigation of the sea-keeping qualities of ships, and thi change of emphasis from that on performance i smooth water is continuing. Mr. Kent does not refe specifically to this trend nor to the results of the mor recent investigations into ocean weather and performance of ships at sea. However, this is not detrimenta to the book, which is mainly a record of Mr. Kent' own experiences and ideas with supporting theor and experiment data, and in the preface he modestl indicates the need for greater knowledge. The worl of naval architecture is indebted to Mr. Kent for putting into a single very readable volume his considere views on the design of ships for service conditions, n doubt matured by leisurely reflexion in retirement.

GEOGRAPHICAL ANALYSIS OF BRITISH WEATHER

British Weather in Maps

By James A. Taylor and R. A. Yates. Pp. xiv+256 (London: Macmillan and Co., Ltd.; New York St. Martin's Press, Inc., 1958.) 21*s*. net.

THIS is an attractively produced book the eleganc of which does great credit to its printers and publishers. The authors, who lecture in the Departmen of Geography at Aberystwyth, define their purpos (p. 39): "the interpretation of the Daily Weathe Report for the non-meteorologist and in particular o (*sic*) the geographer"; elsewhere, "a method o geographical analysis and interpretation of th primary documents of British weather". Introductory chapters discuss fundamentals of Britis weather, the compilation of the Daily Weathe Report, and the prevailing characteristics of ai masses. Thereafter the method is to present well-chosen examples of representative situations, and the to plot weather elements separately and examin their distribution. Upper-air data are mentioned but stress is on the surface map.

The authors' approach is original, and without doub this compilation is useful, although it will mee with some criticism from both geographers an meteorologists. Geographers will note the difficultie arising from plotting temperature using 6-hr. dat and from the omission of upland stations (cf. p. 198) After reading p. 66 the student will be much puzzle by events at Benbecula and Tiree on Fig. 37; and (p. 90) the weather at Dishforth (Fig. 40) is scarcely anomalous under the conditions given. To a geographer, Cape Wrath is not in the Hebrides (p. 207) and West Freugh is not in the Southern Upland (p. 96). Meteorologists will not care much for th method and will find their own points to criticize for example, on pp. 55 and 63 relative and absolut humidity are confused; "the slower rate of cooling at coastal stations" (p. 190) is not well supported by Fig. 70. Noon observations would have made for better discussion; the transitional character of most of our air might have been emphasized more.

There are, however, many admirable diagrams and maps to enliven the reader; for example, those showing visibility (cf. p. 211), cloud and pressure tendency; and while alert-minded students may here and there ask awkward questions, it is good for geographers to be reminded of orographic depressions. Hence, the book will go far to fulfil its purpose; any student who works through this book will gain considerable insight into synoptic meteorology, and will be well equipped to add to his knowledge of British hill weather from other sources. GORDON MANLEY

INDUSTRY AND THE WORKER

The First Principles of Industrial Relations

By Dr. A. E. C. Hare. Pp. vii+146. (London: Macmillan and Co., Ltd.; New York: St. Martin's Press, Inc., 1958.) 12*s*. 6*d*. net.

Productivity and Economic Incentives

By J. P. Davison, P. Sargant Florence, Barbara Gray and N. S. Ross. Pp. 306. (London: George Allen and Unwin, Ltd., 1958.) 35*s*. net.

AN economist, Dr. A. E. C. Hare, of the University of Leeds, has written a book on industrial relations which may well become a little classic. Using knowledge gained from the study of economics, psychology, sociology and law in his quest to find the source of industrial discontents, his book ranges over the whole structure of society, its social organizations and political forms, its religious and ethical norms and its attitudes to property and work. Yet all the time Hare is concerned with those features of industrial relations which make for workers proud of their callings, satisfied with their rewards, and secure in the knowledge that they belong to efficient firms with executives who genuinely believe that good profits and sound industrial relations go hand-in-hand.

Dr. Hare shows, for example, that the common attitude of connecting the development of good industrial relations simply with the avoidance of strikes is a negative approach which begs many questions and leads to more and more industrial unrest. The study of industrial relations should take full account of the assumptions fundamental in the structure of society; the freedom of the individual in thought and speech and of his right to organize with groups of like-minded people for religious, political or economic purposes; the freedom of the individual to buy and sell and to enter any occupation he chooses; the freedom for a man to strive to increase his income and to acquire wealth and so lift his status in the eyes of his fellow-men; the right of a man to acquire and own property and to dispose of it as he pleases. These are fundamental freedoms which give rise to conflicts between themselves; freedom in one direction may have to be restricted in order to permit freedom in another. "The conflicts which arise in industry are the products of a conflict between individuals or groups, each pursuing their economic freedom to increase their income. They also arise from the conflict between the freedom to own and direct how the instruments of production shall be used and the economic freedom to work at any occupation or indeed to work at all. Freedom to direct how the means of production shall be used carries with it economic control over the lives of men and must therefore necessarily conflict not only with their economic freedom but also with many other individual freedoms."

Here lies the root of the problems of industrial relations and, in this masterly little book, which is a model of clear thinking, Hare shows how the State, the employer and the trade unions each have a contribution to make in the never-ceasing struggle to establish industrial harmony. He is wise enough to show that there are no quick or easy remedies based on the latest device.

In his analysis Hare does not minimize the part played by wages as a major cause of industrial discontent; more disputes arise in industry over wages than any other subject. Yet, as the authors of "Productivity and Economic Incentives" show, surprisingly little attention has been paid to the real effects of the economic motive in industry. Industry ceases to be unless it can produce efficiently, but even to-day there is little knowledge of how productivity is affected by the introduction of financial incentive schemes. This has been partly due to the difficulty of obtaining clear cases of an incentive applied in isolation, and partly to the neglect of the subject by psychologists. They have been, as Sargant Florence writes, "only slightly interested in tracing the economic motive or observing the material, economic facts of output, costs, absence and labour turnover".

This composite book has been written by four authors, all members of the Faculty of Commerce and Social Science at the University of Birmingham. The background is described by Prof. Sargant Florence, while J. P. Davison, after measuring their output and earnings, interviewed factory workers to determine their reaction to incentive payment schemes and ancillary matters. These accounts are supplemented by Dr. H. S. Ross, himself a former convener of factory shop stewards, who also supplies a detailed and over-long case-study of trades union and labour reactions to the application of incentives and the industrial relations background in a chosen factory. Dr. Barbara Gray interviewed and obtained the output earnings of laundry workers and shop assistants.

The conclusions of all four investigators were unanimous and clear. The introduction of financial incentive schemes in industry and commerce leads to a considerable increase in the productivity of labour together with an increase in earnings without the workers complaining of undue strain. Few there would be with knowledge of industry who would question the findings of these well-conceived and well-conducted inquiries. Few would argue against their considerable extension.

How, therefore, can their findings be reconciled with the actions of several leading British firms which, during the past few years, have abandoned their piece-work incentive schemes?

It is perhaps significant that those who are advocating the abolition of financial incentive payment schemes are those employed by companies which were among the first to introduce these schemes several decades ago and where they had reached a considerable degree of complexity. The reconciliation of this view—which has led to the abolition of financial incentive schemes in such companies as Ford and Vauxhall—and that put forward by the authors of the book may be due to two reasons. The first is that all factories striving to be efficient must introduce some kind of incentive scheme to determine its optimum rate of output; it is difficult to see how a norm can be established in any other way. The second is that the apparent success of changing from a flat rate of pay system to an incentive scheme or vice versa may be due not to the system of payment at all but to the change; it will be interesting to see whether in a few years time a new management at Ford or Vauxhall may decide the time has come for a change and revert to an incentive system of payment but worked out on lines different from those which formerly prevailed. T. H. HAWKINS

LIBRARIES FOR RESEARCH

Classification and Indexing in Science

By B. C. Vickery. Pp. xvii + 185. (London: Butterworths Scientific Publications; New York: Academic Press, Inc., 1958.) 25*s.*; 5.50 dollars.

IN a recent address in Manchester to the Reference and Special Libraries Section of the Library Association, Mr. D. J. Foskett said that it was intolerable that existing discords between the general classification system and the requirements of modern research should be allowed to continue, and urged the need to adopt new systems as they become necessary so that the results of research can be organized in a way that permits of their effective retrieval. Mr. B. C. Vickery's book, to which Mr. Foskett contributes an introduction, is intended as a contribution to that end. It does not purport to be a manual of classification and indexing but is intended rather to assist those who are concerned with the practical task of constructing systems for retrieving information, whether their concern is limited to classification and indexing or also embraces mechanical selection.

As such this book is primarily a study of method. It considers, step by step, the problems which arise in constructing a faceted classification and then discusses in some detail notational devices which may be used in a classified catalogue. A further chapter considers the new developments in the use of mechanical methods of retrieving information, and discusses the limitations of conventional systems of classification and indexing for this purpose, as well as the capacities of the machines. Due weight is given to the cost aspect, and the reader who follows Mr. Vickery's counsel will not prescribe a sledge-hammer to crush a nut. Finally, after a chapter in which indexing is considered from various points of view, particularly the use of facet analysis to overcome defects in alphabetical indexing, the future trends in information retrieval are briefly outlined, and some of the areas in which further study is required are indicated.

All this is competently and modestly done with no attempt to dogmatize. But the book has a much wider interest than for the specialist. In an opening chapter on the need for classification, Mr. Vickery amplifies the thesis that all forms of information retrieval can and should be based upon a classification of knowledge if they are to function with maximum effectiveness. With the needs of the user firmly in mind, Mr. Vickery sets forth very clearly the difficulties and problems that arise and his exposition should be of real interest to any scientist who is concerned with the problem of indexing and classification in his own particular field. For the most part this is done with admirable lucidity, but for the general reader the explanation of the technique of facet analysis could be clearer, and in view of the general interest of this chapter, Mr. Vickery might with advantage amplify it in a future edition. Also of general interest are the appendix on historical aspects of the classification of science and that giving a theoretical analysis of some general catagories useful in the classification of science. A series of admirable bibliographies enhances the value of the various chapters. R. BRIGHTMAN

TREE PHYSIOLOGY

The Physiology of Forest Trees

A Symposium held at the Harvard Forest, April, 1957. Edited by Prof. Kenneth V. Thimann, with the assistance of William B. Critchfield and Martin H. Zimmermann. Pp. xvi + 678. (New York: The Ronald Press Company, 1958.) 12 dollars.

THE study of tree physiology as a separate branch of plant physiology has been traditionally confined largely to those problems of flow of sap, translocation and growth which assume particular significance in large woody perennials. In recent years, however, interest in the physiology of forest tree species at all stages of growth has grown considerably; besides a rapidly expanding fundamental research programme in forestry, many pure botanists have realized that here is a field which has been relatively little investigated in the light of modern physiological knowledge and techniques. The result has been an impressive expansion of our knowledge concerning tree growth which, until recently, has found little opportunity for collective expression. It was therefore a timely decision on the part of the Cabot Foundation for Botanical Research to arrange this the first international symposium on tree physiology. The publication of the thirty-five papers presented by invited participants provides a wealth of up-to-date information on a variety of topics, covering water relations and sap movement, photosynthesis, biochemistry, mineral nutrition, phloem transport, root growth, photoperiodism, reproduction and various other growth phenomena. Full discussions included with each paper serve as a particularly valuable source of comment, criticism and speculation.

Many of the contributions are primarily of academic interest, others of considerable practical significance in their application to sylviculture and tree breeding. The contents are therefore of interest to both botanists and foresters, and to single out particular papers as being more worthy of mention than others is a difficult task. Students of the classical physiological problems will welcome Scholander's elegant approach to the solution of the air embolism problem confronting the 'cohesion theory', and the articles of Huber and of Zimmermann dealing with phloem transport and the evidence for 'mass flow'. The various papers on photoperiodic responses, despite a certain overlap, and those on factors governing seed germination are well worth reading for both their botanical and forestry interest. Forest geneticists should certainly be stimulated by the papers discussing techniques for inducing early flowering.

On the whole, the publication maintains an excellent standard both as to contents and their reproduction. Despite its wide coverage, it leaves many important problems of tree growth untouched and raises many new ones; but, in filling at least partially a long-felt gap in our knowledge as to how trees function, it deserves, and will undoubtedly receive, a welcome reception. L. LEYTON

AIR SHOWERS OF SIZE GREATER THAN 10^5 PARTICLES*

(4) THE DISTRIBUTION OF NUCLEAR-ACTIVE PARTICLES AND OF MU-MESONS

By J. A. LEHANE, Dr. D. D. MILLAR and M. H. RATHGEBER

The F.B.S. Falkiner Nuclear Research and Adolph Basser Computing Laboratories,
School of Physics†, University of Sydney

THE importance of the nuclear-active cascade in the development through the atmosphere of an extensive shower of cosmic rays is now well established, although the details of the high-energy nucleon – nucleus interactions which generate the cascade are still largely unknown. Indeed, only from observations on the extensive air showers can one hope to gain insight into such high-energy phenomena.

Among the different types of particles in an air shower the nuclear-active particles, both nucleons and π-mesons, are produced directly in these nuclear interactions. The μ-mesons are produced at one stage removed from them by the decay of π-mesons. Investigations of these components are therefore likely to be of greater value in elucidating the nature of the interactions than are investigations of the electron component, since this last is detected after many generations of the electron-photon cascades which have been initiated by the decay of neutral π-mesons.

The experiment reported in this article was carried out in the University of Sydney (40 m. above sea-level). It was designed to determine the lateral distribution of the density of nuclear-active particles (which we shall refer to as 'nucleons' hereafter, although it must be understood that charged π-mesons are included in the term) and of μ-mesons, in air showers the measured sizes of which range from 3×10^4 to 6×10^6 charged particles. The distributions were determined for distances from the shower core of up to 50 m.

The results are consistent with earlier experiments and confirm quantitatively the fact that small showers are relatively richer both in nucleons and μ-mesons than are large showers[1]. The experimental observations at sea-level are compared with similar observations made by Vavilov *et al.*[2] at an altitude of 3,860 m., and the implications of this comparison are briefly discussed. From both sets of results we obtain figures which may be compared with the theoretical calculation of Ueda and Ogita[3] for a primary energy of 10^{15} eV. and best agreement is obtained for an inelasticity of 0·3 in the nuclear collisions, meaning that only 30 per cent of the energy of the primary particle is lost to secondary particles in each collision. However, no existing theoretical calculation of the development of the mixed cascade can yet be shown to account for all the experimental results, and it is suggested that the results are now sufficient in quantity for an extended programme of theoretical computation to be worth while.

Experimental Arrangement

A penetrating-particle detector has been included in the University of Sydney's array of scintillation counters used for the detection and analysis of extensive air showers. The array and the method of analysis of the results obtained from it, whereby the size and location of the core of each shower are determined, have already been described[4].

The construction of the penetrating-particle detector is shown diagrammatically in Fig. 1. It consists of three trays, one above the other, each containing 46 Maze-type Geiger counters, of length 50 cm. and diameter 2 cm., embedded in a lead pile. Above the topmost tray is 15 cm. of lead and 1·25 cm. of iron and between the trays is 5 cm. of lead and 1·25 cm. of iron. On the bottom is a layer of lead 2·5 cm. thick. Any particle entering the side of the pile without scattering must traverse at least 15 cm. of lead in order to be detected.

Each counter is connected to its own coincidence and memory unit, a two-grid thyratron, the condition of which determines whether or not a particle has traversed the counter in coincidence with an air shower detected by the scintillator array. The stored information from all the counters in the penetrating-particle detector is punched on paper tape which may then be examined visually or analysed by the electronic computer SILLIAC.

Classification of Events

The distinction between events caused by an incident μ-meson and by a nucleon is in principle simple. A μ-meson, provided it has an energy greater than 380 MeV., will traverse all three counter trays and discharge three colinear counters, one in each tray. A nucleon, on the other hand, will interact in the lead or the iron, producing secondary particles

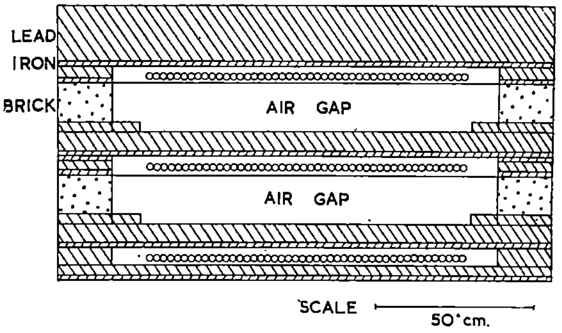

Fig. 1. Construction of the penetrating-particle detector

which will discharge several counters. The lower limit to the energy of such nucleons is not well defined by the number of counters discharged but is likely to be of the order of several GeV. (ref. 5). The electrons of the air shower are stopped by the shielding material. This classification into μ-meson, and nucleon, events is, however, liable to be affected in the following ways.

---

A μ-meson traversing a tray of counters may be accompanied by a knock-on electron which traverses a second counter in the tray, thereby simulating a low-energy nuclear interaction. The magnitude of this effect was determined in a subsidiary experiment in which 'straight-through' μ-mesons of the normal cosmic-ray flux which traversed the detector were selected by a counter telescope, the output from which was used to trigger the recording apparatus. The number of events in which one adjacent counter was struck, in addition to the three collinear counters traversed by the μ-meson, was found to be a fraction $0 \cdot 11 \pm 0 \cdot 01$ of the number of traversals. For the air-shower events the corresponding fraction was $0 \cdot 12 \pm 0 \cdot 02$ of the events in which three collinear counters were traversed. In view of this agreement, all events in which one counter was struck in one tray adjacent to the counters defining the trajectory of the μ-meson were classified as 'μ-meson induced'.

Because of the thickness of the walls of the counters, there exists a geometrical inefficiency for detection of particles. The subsidiary experiment mentioned above showed that there was a 10 per cent probability that a μ-meson traversing the detector would fail to traverse the sensitive volume of a counter in one of the trays, a result in agreement with the geometry of the trays. Consequently it was decided to accept as μ-meson events those in which only one counter in each of two trays was traversed, provided the supposed μ-meson trajectory was not inclined at an angle greater than about 40 deg. to the vertical. No correction was applied to the observed number of μ-mesons for those events which missed detection in more than one tray, since their number should be less than 1 per cent of the total number of observed μ-mesons.

Also omitted from the μ-meson class of events were those μ-mesons which produced knock-on showers discharging several counters and therefore were classified as nucleon events. From the subsidiary experiment mentioned earlier such events produced by the penetrating cosmic-ray flux, and which therefore included a contribution from genuine nucleons, occurred with a frequency less than 1 per cent of the μ-meson traversals. No correction has therefore been made for such events.

In selecting the events induced by the interacting nucleons, two different criteria have been used. For the first of these, the minimum requirement is that one counter be struck in at least two trays together with at least one non-adjacent counter within a distance of five counter widths. The second, more rigorous criterion, demanded that at least three counters be struck in each of two adjacent trays. These could be ascribed to higher-energy nucleon events. It is possible that in the first of these classes of events there will be a higher proportion of misclassified μ-meson events than in the second. No evidence for this has been observed, however, in comparing the lateral distributions of all nucleons, selected according to the first criterion, and of the high-energy nucleons, selected according to the second.

It is possible for a μ-meson and a nucleon to traverse the apparatus together, and frequently such events were indeed observed. However, in no single nucleon event is it possible to exclude the presence of a μ-meson traversal masked by the nucleon interaction. Rather than carry out the statistical procedure necessary to make use of such double events, the μ-meson distributions were obtained by excluding from the analysis all showers accompanied by nucleon events. It is thereby assumed that the μ-mesons and nucleons are spatially uncorrelated.

An incident nucleon may pass through the detector without undergoing any detectable interaction. The mean free path for interaction has been taken as 160 gm. cm.$^{-2}$ in lead and 130 gm. cm.$^{-2}$ in iron, and it is estimated that one-sixth of the nucleons will therefore traverse the detector without interacting. Of these, we have assumed that some 60 per cent are charged particles[6] which will be then wrongly classified as μ-mesons. In deducing the distributions of μ-mesons, 10 per cent of the corresponding nucleon density has accordingly been subtracted from that of the μ-mesons at each distance from the shower core. This correction may in fact be too small, since a non-interacting proton of energy 600 MeV. may traverse the detector simulating a μ-meson, whereas an interacting nucleon must have an energy of several GeV. to produce a detectable interaction. The true μ-meson distribution may therefore be even flatter near the shower core than we find.

Analysis of Results

A total of 3,240 showers was available for which the shower size and the location of the core were determined, the former to within limits of + 20 per cent and − 10 per cent, the latter with an uncertainty about ± 4 m. These showers were classified in 25 groups—in five ranges of shower size from 0·1 to 1, 1 to 3, 3 to 6, 6 to 10 and 10 to 60 × 10^5 particles —and in five ranges of distance of the penetrating particle detector from the shower core—from 0 to 50 m., in 10 m. intervals. For each of the 25 groups the mean shower size, N_i ($i = 1, \ldots, 5$), and the mean distance from the core, r_j ($j = 1, \ldots, 5$), were determined.

If for a class of showers, all of size N_i, the density of μ-mesons or of nucleons at a distance r_j from the core be denoted by x_{ij}, then the probability of observing m_{ij} showers in which one or more of the particles under consideration has traversed the detector, and n_{ij} showers in which no particle has traversed it, is proportional to :

$$P(m_{ij},n_{ij}) = [1 - \exp(-Ax_{ij})]^{m_{ij}} [\exp(-Ax_{ij})]^{n_{ij}}$$

where A is taken as the area of one of the trays of Geiger counters for μ-mesons, and as five-sixths of this area for nucleons, thus taking into account the probability for interaction by the nucleons discussed above.

Using the values of m_{ij} and n_{ij} determined experimentally, this probability function was computed, as a function of the variable x, for each of the 25 groups of showers and the probability distributions were drawn. From these were determined the median values of x and the quartile values.

In Figs. 2 and 3 are plotted the median values of x_{ij} in particles per square metre divided by N_i, the mean shower size, as a function of r_j in metres. The error limits shown are typical for all points and correspond to the quartile value of the distributions

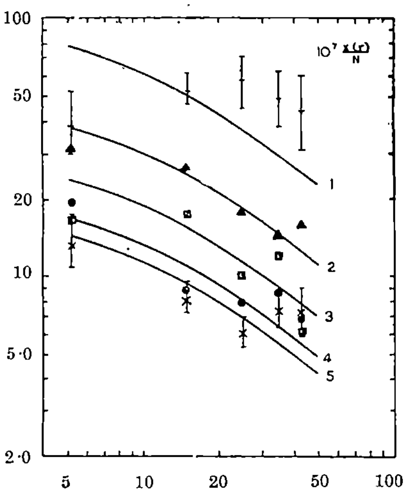

Fig. 2

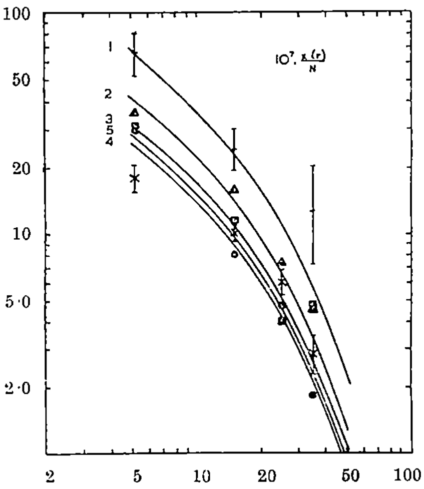

Fig. 3

Fig. 2. Density of μ-mesons $x(r)$ in particles/m.^{2} divided by the mean shower size in scintillator particles as a function of distance from the shower core r in metres. (+ denotes showers of mean size $\bar{N} = 6{\cdot}2 \times 10^4$; △, $1{\cdot}9 \times 10^5$; ▣, $4{\cdot}4 \times 10^5$; ⊙, $7{\cdot}8 \times 10^5$; ×, $1{\cdot}8 \times 10^6$)

Fig. 3. Density of nucleons shown in the same way as for μ-mesons in Fig. 2

in x. These limits then correspond to probable errors. In Fig. 2 the derived density of μ-mesons has been corrected at each distance for contamination by non-interacting charged nucleons by subtracting from it 10 per cent of the corresponding nucleon density as given in Fig. 3.

It is clear that the statistics are not yet good enough to determine whether there is a change in the shape of the functions for μ-mesons and nucleons relating x/N and r as the shower size increases. It is also clear, however, that for any fixed distance from the core the ratio x/N increases with decreasing N: small showers are relatively richer in both μ-mesons and nucleons than are large ones.

The curves which have been fitted to the points of Figs. 2 and 3 were deduced as follows. It was assumed that the density of both μ-mesons and of nucleons was expressible in the form $x(r) = N_i f(r)$. For each of the five mean distances, r_j, the expression $\prod_{i=1}^{5} P(m_{ij},n_{ij})$ was computed as a function of f, and from the probability distributions so obtained the median values and the quartile values of f were again obtained for each distance r_j. The radial distributions so obtained were plotted for μ-mesons and for nucleons. Again, 10 per cent of the nucleon ordinates were subtracted from the μ-meson ordinates at each distance. A smooth curve was drawn through these points. These curves were then fitted to the points of Figs. 2 and 3, using the computed probability distributions in x_{ij} by a maximum likelihood method.

As a second approximation it was assumed that $x(N,r) = Nk(N)f(r)$, where $k(N)$ is a slowly varying function of N, and is in fact given by the separation of the curves of Figs. 2 and 3. These values of $k(N)$ as a function of N are plotted in Figs. 4 and 5, taking in each case $k(N) = 1$ for a shower size $N = 10^6$ particles. The errors quoted on the values of $k(N)$ are probable errors derived in the curve-fitting procedure. Taking these values of $k(N_i)$ and putting $x(N_i,r_j) = N_i k(N_i) f(r_j)$, the expression $\prod_{i=1}^{5} P(m_{ij},n_{ij})$ was again computed as a function of $f(r_j)$. The probability distributions were again plotted, and median and quartile values of f determined for each r_j. These values of $f(r)$ are plotted in Figs. 4 and 5 for μ-mesons and nucleons. Again the μ-meson ordinates have been corrected by 10 per cent of the nucleon ordinates at each distance. The calculated values of $f(r)$ so obtained were consistently about 10 per cent greater than those already obtained by averaging over showers of all sizes. This similarity in shape of the distribution curves at the two levels of approximation arises from the fact that the shower-size distributions in each distance class were similar.

In Fig. 5 we have also plotted the lateral distribution function for the high-energy nucleons. Because of limited statistics only the first approximation procedure was adopted. There is no significant difference between the two distributions. The curves drawn through the nucleon points have the analytical form $f(r) = A\exp(-r/20)\ r^{-1/2}$ with $A = 7{\cdot}5 \times 10^{-6}$ for the total nucleons, 3×10^{-6} for the high-energy nucleons.

If then the density of μ-mesons and of nucleons may be expressed in the form $x(N,r) = N\,k(N)f(r)$, so that the radial part of the distribution $f(r)$ is independent of N, then the curves of Figs. 4 and 5, giving $k(N)$ as a function of N, and $f(r)$ as a function of r, define x.

Discussion

From the experimental results presented in Figs. 2 and 3 one finds that, at a distance of 5 m. from the

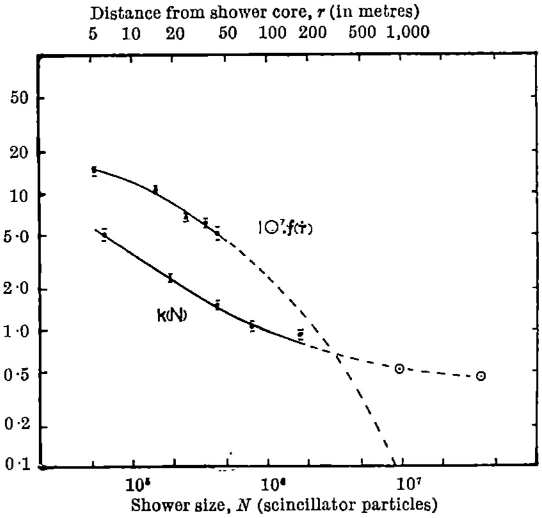

Fig. 4. Density of μ-mesons expressed as a function of shower size, N (scintillator particles), and the distance from the shower core, r, in metres. The density of μ-mesons is given by $x(N,r) = N\,k(N)f(r)$ per sq. metre. The extrapolated part of the curves are obtained from the Harwell observations

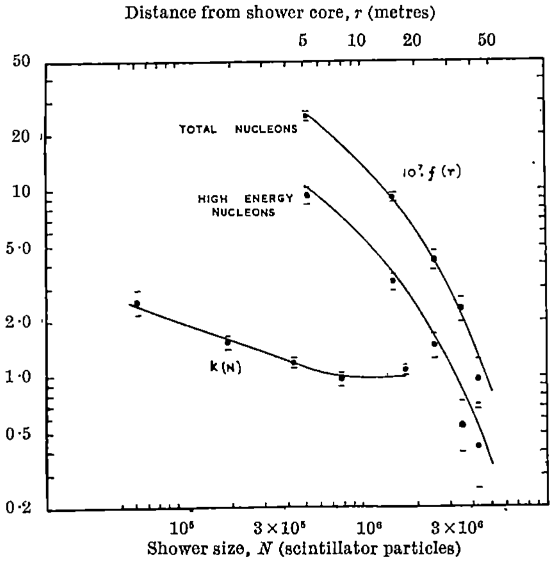

Fig. 5. Density of nucleons expressed in the same way as for the μ-mesons of Fig. 4. High-energy nucleons are those for which the minimum number of Geiger counters discharged is greater than for the total nucleons

shower core and in a shower of size 10^5 particles the density of nucleons and of μ-mesons are both $\approx 0{\cdot}5$ m.$^{-2}$. The total particle density, estimated from our shower structure function[4], is 35 m.$^{-2}$. For a 10^6-particle shower, on the other hand, the densities of nucleons, μ-mesons and total ionizing particles are respectively 3, 1·7 and 350 m.$^{-2}$. Since these nucleon densities refer to nucleons detected by our apparatus and therefore having energies greater than several GeV. (and this lower limit may be as high as 10 GeV.) we should expect a density of low-energy nucleons appreciably higher than these quoted values. Such low-energy nucleons would then constitute an appreciable fraction of the total particle density near the core and may be expected to play a significant part in determining the form of the shower-structure function of all ionizing particles near the core. Further evidence confirming the existence of a high relative density of lower-energy nucleons near the shower core has been obtained from a detailed comparison between the response of a scintillation counter and of a Geiger counter[7].

Several experiments have been carried out in the past using arrays of shielded and unshielded trays of Geiger counters in which the rate of coincidences between trays has been used to obtain an average value of the density of penetrating particles—both μ-mesons and nucleons—relative to that of all ionizing particles in the showers recorded. Such experiments at sea-level have given a value of about 2·5 per cent for the ratio of penetrating particles to total particles, a value which depends, however, upon the way in which the showers are selected[8]. The ratio of μ-mesons to nucleons has also been determined in similar experiments and found[9] to be about 2 : 1. From our results these figures can be obtained in a shower of size 10^6 particles and at a distance of 40 m. from the shower core. However, the interpretation of the average values obtained experimentally in terms of an average shower of size 10^6 particles falling with its core 40 m. away from the detecting apparatus is not particularly significant, since the shower-structure functions for μ-mesons, for nucleons, and for total particles in a shower differ from each other markedly, both in their dependence upon radial distance, r, and upon shower size, N. There appears to be no great difficulty in reconciling these earlier experiments with the results presented here.

In Fig. 4 are presented the results of Fig. 2 for the μ-meson distributions in the form $x(N,r) = N\,k(N)\,f(r)$ particles per square metre. Fig. 4 also shows the sea-level results reported by the Harwell group[10]. The extrapolated part of the $f(r)$ curve, from 40 m. to 1,000 m., is the curve for $x(r)$ given by them for showers of mean size $6{\cdot}7 \times 10^6$ particles, joined to our own at 40 m. Since they were using a Geiger counter array we have multiplied their shower size by a factor of 1·4 in order to convert it into the shower size as it would be estimated by our scintillator array[11]. The normalization of the two curves at 40 m. leads to a value of k for such a shower size of 0·52. Similarly, the value of $k(N)$ for their larger size group has been obtained from their quoted density of μ-mesons in such showers at 100 m. from the core and from the $f(r)$ value at this distance as given by the extrapolated curve of Fig. 4. The radial distributions given by the Harwell group for the two mean shower sizes do not differ in form significantly from each other.

The results from Harwell on the density distribution of nucleons is of limited statistical significance since their shower cores are located with large uncertainty. However, they do obtain an estimate of the total number of nucleons detected, from the total number of nucleon events detected in showers of mean size $6{\cdot}7 \times 10^6$ charged particles. Their estimated number is $(4 \pm 2) \times 10^4$. Integration of our analytical-structure function leads to a predicted number in such showers of $3{\cdot}8 \times 10^4\,k(N)$ of total nucleons, of which five-sixths would be observed to interact in a detector such as our own.

One may consider the data of Figs. 4 and 5 merely as a convenient way of representing the experimental observations. If, on the other hand, it is assumed that the shape of the distribution function $f(r)$ is strictly independent of shower size N then the total numbers of nucleons and of μ-mesons are proportional to $Nk(N)$. We then find from the results presented in Figs. 4 and 5 that the total number of nucleons in showers of size 6×10^4 to 8×10^5 is proportional to $N^{0\cdot6 \pm 0\cdot1}$, whereas for μ-mesons it is proportional to $N^{0\cdot4 \pm 0\cdot1}$. From the additional μ-meson data of the Harwell group there is evidence that the exponent in the relation may increase at large values of N.

Experiments very similar to our own have been carried out at an altitude of 3,860 m. in the Pamirs by Vavilov *et al.*[2], and it is of interest to compare the results obtained at the two altitudes. In showers of size less than 2×10^5 they find the number of nucleons to be proportional to $N^{0\cdot2}$ and for larger sizes it is proportional to $N^{1\cdot0}$. The change which occurs at a shower size of 2×10^5 particles they interpret as indicating a change in the nature of the high-energy interaction at an energy of 10^{15} eV., their estimate of the primary energy of such a shower. If this were so we might expect that our sea-level showers of size greater than 2×10^5 particles, initiated by higher energy primaries, would contain nucleon numbers proportional to $N^{1\cdot0}$ rather than $N^{0\cdot4}$. The interpretation given above of the results from the Pamirs is not, therefore, likely to be correct.

In comparing further the results obtained at sea-level and at mountain altitudes we may take the number of nucleons at sea-level, n_1, in a shower of size N_1 to be proportional to $N_1^{\gamma_1}$, and at mountain altitudes the corresponding numbers of nucleons, n_2,

Table 1. THEORETICAL RESULTS OF UEDA AND OGITA FOR A SHOWER OF PRIMARY ENERGY 10^{15} EV., COMPARED WITH THE CORRESPONDING EXPERIMENTAL RESULTS AT TWO ALTITUDES

$\eta =$	Sea-level, 1,030 gm. cm.$^{-2}$			Mountain altitude, 640 gm. cm.$^{-2}$		
	N	n_{nucleons}	n_{μ}	N	n_{nucleons}	n_{μ}
0·3	$3 \cdot 6 \times 10^5$	1,900	4,500	$7 \cdot 8 \times 10^5$	2,300	2,300
Experimental	$5 \cdot 0 \times 10^5$	2,100	0·65	$7 \cdot 8 \times 10^5$	2,100	0·48
0·5	$2 \cdot 4 \times 10^5$	450	7,000	$9 \cdot 7 \times 10^5$	1,800	6,000
Experimental	$3 \cdot 4 \times 10^4$	1,600	0·54	$9 \cdot 7 \times 10^5$	2,900	0·56
1·0	$1 \cdot 3 \times 10^5$	100	8,700	$1 \cdot 3 \times 10^6$	1,000	8,000
Experimental	$1 \cdot 8 \times 10^5$	1,000	0·43	$1 \cdot 3 \times 10^6$	3,900	0·74

as proportional to $N_2^{\gamma_2}$. Then if the shower size is attenuated by a factor A between these two altitudes, so that $N_2 = AN_1$, we find that the nucleons will be attenuated by a factor n_2/n_1, which is proportional to $A^{\gamma_2}N_1^{\gamma_2-\gamma_1}$. The attenuation factor, A, appears to be independent of shower size and, corresponding to constant attenuation length of 190 gm./cm.^{2} (ref. 12), is equal to 8. We find from our results that $\gamma_1 = 0 \cdot 6 \pm 0 \cdot 1$, and from the Pamirs results for the corresponding showers eight times the size of our own, that $\gamma_2 = 1 \cdot 0 \pm 0 \cdot 1$. The attenuation factor for the nucleons is thus dependent on shower size to the extent that $\gamma_2 - \gamma_1$ may be considered different from zero. Similarly, the μ-meson results indicate that the attenuation factor is again dependent upon shower size, and as for the nucleons, the μ-mesons are less attenuated in small showers than in large.

It may be unwise, however, to carry too far an argument which assumes that a given shower size at sea-level may be related uniquely to a corresponding shower size at mountain altitude, and that this in turn may be related uniquely to a corresponding energy of the primary particle. Fluctuations in the development of the air shower, together with the existence of a spectrum of energies and of masses of the air-shower primaries, may modify considerably the interpretation of the experimental data.

A further point of comparison between the mountain and the sea-level results is afforded by the forms of the distribution functions for μ-mesons and for nucleons which have been determined at the two altitudes. It has already been noted by the Harwell group that the Pamirs μ-meson distribution falls off more rapidly at large distances than does theirs. On the other hand, the structure function which we have used as a good fit to our sea-level results for nucleons may be also fitted to the experimental points for two shower sizes quoted by Vavilov *et al.* Their nucleons were detected in a similar apparatus and were selected according to the same criterion as our own. There is consequently no indication that the nucleons are spread out more at sea-level than at mountain altitude.

Lastly, the results have been compared with the theoretical predictions of Ueda and Ogita[3]. Those authors calculated the longitudinal development of a model air shower initiated by a primary particle of energy 10^{15} eV. and derived as a function of depth in the atmosphere the total numbers of electrons, μ-mesons and nucleons for different values of the inelasticity, η, of the nucleon–nucleus collisions. Table 1 gives the theoretical predictions of the total numbers of electrons, of nucleons of energies greater than 10 GeV. and of μ-mesons produced by decaying π-mesons above the same energy-limit, for different values of η. Also given are the estimates of these numbers from the experimental observations. The nucleon numbers at sea-level are those obtained by integrating our analytical expression for $f(r)$. The numbers of nucleons at mountain altitude are obtained by increasing the values quoted by Vavilov *et al.* by 30 per cent, to include a contribution from nucleons at distances greater than 50 m. The total numbers of μ-mesons have not been calculated since the contribution from large distances where the structure function is not well defined is considerable; instead we have quoted a number proportional to the density of μ-mesons at a distance of 20 m. from the core of the shower, neglecting the fact that the μ-meson distribution at mountain altitude appears to be narrower than at sea-level. If, in fact, both at sea-level and at mountain altitude, the nucleons detected in the experiments are of energy greater than 10 GeV. and the μ-mesons detected are proportional to the number which have come from π-mesons of energy greater than 10 GeV., the data are seen to be in reasonable agreement with theoretical expectation for $\eta = 0 \cdot 3$. Again, however, it should be pointed out that this one-to-one correlation between primary energy and detected shower size at two altitudes may be of doubtful validity.

Summary

We have determined the nucleon and μ-meson density distribution for showers of size 5×10^4 to 2×10^6 scintillator particles out to distances of 40 m. from the shower core. There is no significant evidence that the forms of the distribution functions change with shower size, although additional statistics will be required in order to determine whether this is really the case.

On the assumption of a constant form for the radial structure function, the number of μ-mesons in the showers recorded varies as $N^{0 \cdot 4 \pm 0 \cdot 1}$ and of nucleons, as $N^{0 \cdot 6 \pm 0 \cdot 1}$, within the range of shower sizes investigated. Comparison with similar experimental observations at mountain altitude indicates, on this assumption, that the attenuation-length of nucleons and of μ-mesons is longer in small showers than in large.

A comparison has been made with the theoretical results of Ueda and Ogita for one primary of energy 10^{15} eV. and this leads to agreement with a value of 0·3 for the inelasticity of the high-energy collisions of the nucleon cascade. An extension of the theoretical calculations, in the first instance to cover a range of the primary energy spectrum, and to include the effects of fluctuations in depth of the first collision, would probably allow a more detailed and a more meaningful comparison to be made with all the experimental data which are at present available.

Our thanks are due to Prof. H. Messel and to the Nuclear Research Foundation for the provision of the experimental facilities with which this work was carried out. It is a pleasure to acknowledge the large part played by the other members of the Air Shower Group in running the experiment and in discussion of the results. One of us (J. A. L.) has been supported in this work by a grant from the Australian Atomic Energy Commission.

NUTRITION AND TEETH

THE Nutrition Society symposium on the relationships between nutrition and the growth and health of teeth was held at the London Hospital Medical College on October 4, when the chair was taken by Lady Mellanby. The meeting opened with a general review by Prof. F. C. Wilkinson.

The structure of teeth was dealt with by Prof. A. I. Darling, and their embryology, with particular reference to the histochemistry, by Dr. R. Ten Cate. The tooth consists largely of dentine, the material which gives it its elasticity. Whereas root dentine is covered by a thin layer of cementum, crown dentine is covered by enamel. At the centre is a cavity containing the dental pulp. The tooth is slung in its sockets by the fibres of the periodontal membrane which stretch from the bone of the alveolus to the cementum, and at its neck is an attachment between the oral mucosa and the enamel which is itself of ectodermal origin. Chemically, dentine contains about 5 per cent water, 75 per cent other inorganic constituents, mainly hydroxyapatite, and 20 per cent organic constituents[1], mainly collagen, but with small amounts of citric acid, insoluble protein, mucopolysaccharides and fat. Structurally, it is composed of a collagenous matrix which, when calcified, forms its main bulk, through which run the dentinal tubules from the pulp to the amelodentinal junction.

As the tooth develops, a series of changes occur which eventually determine the pattern of the crown, after which the dentine and enamel are elaborated. The formative cells of the dentine, the odontoblasts, are rich in carbohydrate and nucleic acid. Their precise function remains obscure, but close by is the sub-odontoblastic layer rich in alkaline phosphatase activity and with a high content of ribonucleic acid, which probably indicates protein metabolism[2]. The dentine matrix consists of a cementing substance and the so-called fibres of von Korff, which arise in the sub-odontoblastic layer and which gradually change from pre-collagen to collagen. As the matrix becomes calcified the odontoblasts retreat, leaving behind the processes which become incorporated in the tubules running through the dentine. With ageing of the tooth, these tubules close down and are eventually obliterated, perhaps by calcification within the tubule.

Mature dental enamel, consisting of approximately 0·5 per cent of organic material and 99·5 per cent of inorganic salts and water[3], is the hardest tissue in the body—about as hard as sapphire. The process of amelogenesis consists in the formation of an enamel matrix and in the calcification of the enamel. The enamel-forming cells, the ameloblasts, produce at their formative ends Tomes processes which become the pre-enamel rods into which calcium salts are precipitated. Initially, ameloblasts are rich in glycogen, which disappears as the Tomes processes are elaborated. This may represent a phosphorolytic degradation of glycogen to hexosephosphate esters utilized in the synthesis of acid mucopolysaccharide of the enamel matrix. In amelogenesis, as in dentinogenesis, the formative cells are devoid of alkaline phosphatase and yet exist close to cells rich in the enzyme where, it can be postulated, the mucopolysaccharide is made[4]. This has the property of imbibing water, and probably plays an integral part in forming the crown. Calcification starts soon after the deposition of the matrix, which consists mainly of keratin but contains some soluble protein and carbohydrate, and is probably not completed until shortly before eruption. Enamel is made up of prisms arranged in a complex manner. Soluble organic material lies between them and at their cores, while the prism sheaths are keratinous. The inorganic part of the enamel is almost certainly a hydroxyapatite, with some carbonate adsorbed on to the surface of the lattice, and trace elements such as fluorine, copper and iron actually within or also adsorbed on to the surface of the lattice. The trace elements occur almost exclusively in the surface enamel.

Cementum is very like bone, and consists of a collagenous matrix in which calcium salts are deposited. The dental pulp is the remnant of the organ forming dentine and consists mainly of connective tissue cells with a layer of odontoblasts next to the dentine. It communicates with the periodontal membrane, from which it receives its nervous, vascular and lymphatic supply. Nerve fibrils reach the pulp in large numbers and branch beneath the odontoblastic layer. From there, nerve fibrils pass into the uncalcified layer of pre-dentine and probably into the dentine[5], but not the enamel. The vascular and lymphatic supply is rich and closely related to the supply to the periodontal membrane. It seems that there are pathways from the pulp to the oral surface and to the periodontal membrane and *vice versa*, but how they are used in life for the purposes of exchange is still unknown. Exchange in dentine is probably much less than in bone, and enamel is more stable still. When enamel is impermeable the barrier is probably at the enamel surface. The precise role of nutritional factors in the formation of the different parts of teeth has not been elucidated, but it seems that if such factors are to affect the resistance of enamel to attack they must act during the formative period.

Dr. E. W. Bradford stressed that far more teeth are lost by the periodontal diseases, which affect the gum, the alveolar bone, the periodontal membrane and the cementum, than by dental caries. These are of three groups: inflammation of the gums or gingivitis; periodontitis simplex or destruction of the supporting tissues by bacteria or tartar; periodontitis complex or destruction of the tissues for no local reason. They can be considered as a battle between the invasiveness of bacteria and the accumulation of tartar, and the resistance of the periodontal tissues. The result varies greatly between individuals, for reasons almost unknown. The effect of food can be local or systemic. Locally, a high carbohydrate diet stimulates the secretion of saliva with a high water-content and rich in inorganic salts which can form tartar. The proportion of tartar which accumulates on the teeth varies with the amount of chewing, which at all ages promotes the health of the teeth. Thus the more fibrous the diet the better. Much less is known about the systemic effect of diet. In gingivitis and periodontitis simplex, dietary deficiencies are rarely the primary cause. Deficiency of vitamin C or of vitamin D and calcium can be contributory, though probably not causative, in periodontitis complex. Shortage of one or another essential amino-acid in the supporting tissue might be the decisive deficiency and is ripe for investigation.

Dental caries is the result of bacterial attack on the surface of the tooth: the point of interest is what starts the attack. Dr. R. L. Hartles and Mr. G. L. Slack described the incidence, since the beginning of the Second World War, of dental caries in Britain[6] and other countries[7], and gave as the most likely explanation of reduced incidence in war-time the reduced consumption of fermentable carbohydrate. They discussed the results of experiments on rats[8], hamsters[8] and monkeys[9] with natural and high-sugar purified diets, which suggest that such a purified diet is cariogenic and more so if fed during the development of teeth, but that the natural diet fed during development bestows some protection, probably in its mineral fraction, against subsequent exposure to the purified diet.

Dr. G. N. Jenkins also described experiments which suggest the presence of protective factors, possibly buffers, calcium and phytates in crude cane juice, black treacle and high-extraction flours. There was general agreement that the only factor which has been proved to be of value in reducing the incidence of caries in man is the fluoride ion, which makes the enamel more resistant to dissolution by acids: it may act as an enzyme poison preventing the formation of acids. Dr. Jenkins mentioned the possibility that the initial attack on enamel might be made by proteolytic bacteria and might result in decalcification at neutral or alkaline *p*H, but based his review of the environmental aspects of dental caries on the idea that the acids formed from carbohydrate by oral bacteria are the major factor in the development of caries. He described experiments[10] which lead to the conclusion that carbohydrate causes the *p*H of the dental 'plaque' to fall from 7·0 to about 5·0, and that at a critical point, varying with individuals but somewhere between 5·5 and 5·0, the ionic concentrations of the saliva are no longer able to prevent dissolution of the enamel. The more rapid the flow of saliva, the higher the *p*H and buffering power[11]. Thus, tough foods and vigorous chewing help to prevent the saliva reaching the critical *p*H; frequent carbohydrate meals[12] help to bring it there.

The general impression that sufficient protein, mineral and vitamin constituents are necessary for the formation of sound teeth, but that their health can be lost by much soft carbohydrate and insufficient chewing found some support in an archæological review by Mr. D. R. Brothwell. He took the meeting back half a million years to show that signs of dental disease had been found even among early hominid groups[13], and 15,000 years ago among Neanderthal man[14]. His conclusions were that the incidence of dental disease was low in neolithic times when teeth may have been helped by the rough nature of the food consumed, that, in general, dental health declined thereafter, and that for the population of the British Isles the causative factors were the introduction of sugar in the twelfth century and refined flour in the nineteenth. It is clear, however, that even without these adjuncts of civilization neither man nor ape was immune from dental disease.

A combined attack of dentist and dietitian on gross caries in young children was described by Mr. A. M. Horsnell and Mrs. E. Scott. While carious primary teeth can be filled, for treatment to be satisfactory the carious process must first be stopped. This has been achieved by giving dietary advice based on an assessment of the nutritional value of the diets of the patients. Dietary results showed a fairly consistent pattern of snacks between meals, low intakes of protein, calcium, and sometimes iron and some vitamins, and high consumption of carbohydrate. The advice given was to emphasize the importance of milk, vegetables and fruit, such as a raw apple, and a good breakfast containing a source of protein (to avoid the tendency for a mid-morning carbohydrate snack); that no snacks should be taken between meals and that any sweets should be eaten with meals. Dental and general health of the children can be improved when the co-operation of parents and children has been won. To the audience, somewhat bemused by the complexities of the biochemistry of dental development and destruction, this clear demonstration of the effectiveness of the most promising regimen for the protection of teeth was a joy.

The papers read at the symposium will be published in full in the first issue of Vol. 18 of the *Proceedings of the Nutrition Society*, which will appear in March 1959. D. F. Hollingsworth

OBITUARIES

Sir Gilbert Walker, C.S.I., F.R.S.

SIR GILBERT WALKER died on November 4, some four months after his ninetieth birthday. For half a century his has been a prominent name in meteorological circles, and in recent years one was apt to forget that he had been elected a Fellow of the Royal Society for original work in dynamics and electromagnetism before ever he turned his thoughts to meteorology.

Walker went up to Trinity College, Cambridge, from St. Paul's School with a mathematical scholarship. He fully confirmed his early promise on graduating as the Senior Wrangler in the Mathematical Tripos of 1889, an achievement that was followed in due course by election to a fellowship of Trinity and then to a lectureship, both of which he held until going to India. From 1892 onwards he published a series of papers on the theory of electromagnetism, for one of which he was awarded an Adams Prize in 1900. In the same period he was showing a keen interest in dynamical problems, with papers on such subjects as the motion of elongated projectiles, dynamical tops and boomerangs, in which his interests were not wholly theoretical, for he became expert as designer and thrower of boomerangs, and indeed was known in the Cambridge of those days as 'Boomerang Walker'. It is a matter for some regret that his article on "Spiel und Sport" in the great "Encyklopädie der Mathematischer Wissenschaften" was never well known to his own compatriots.

Walker went to India in 1903 to succeed Sir John Eliot as director-general of observatories. The great Indian famine of 1899–1900 was still very much in people's minds and, as it were, challenged Walker to attempt to solve the very complex and difficult problem of forecasting the monsoon rainfall. The physical causes that produce the fluctuations from year to year defied and still defy detection. Walker decided to apply the statistical methods of correlation and soon made the subject of seasonal 'foreshadowing' by these methods peculiarly his own. His investigations, beginning with the search for relationships between previous weather over different parts of the globe and the Indian monsoon rainfall, developed into an examination of the interrelations of world-wide variations of weather, contemporary and consecutive. His papers are a mine of statistical information on world weather, interspersed with concise, critical and acute comment. Of the more important generalizations that emerged, there was one that he called the Southern Oscillation, which may be described as a tendency for air to disperse from the Pacific area at the same time as air accumulates in and around the Indian Ocean. The monsoon plays a part in the Southern Oscillation, out of the elements of which he evolved a formula for 'foreshadowing' monsoon rainfall, which has continued in use in India with but little amendment. Walker would not claim to have solved the monsoon problem, but he pointed a way, and the value of these papers can scarcely be overestimated.

Living in the Simla hills, Walker was fascinated by the soaring flight of birds, at first as a hobby, then as a study on which he wrote several papers, including the article in the "Encyclopædia Britannica" on animal flight.

After retiring from India in 1924, Walker succeeded Sir Napier Shaw as professor of meteorology at the Imperial College of Science and Technology, London. One of the subjects to which he turned his own and his pupils' attention was the cellular structure of an unstable fluid. In striking laboratory experiments they obtained a variety of cellular forms—polygons, transverse and longitudinal vortices—by varying the rate of shear in the fluid, and they were able to show that this physical process explained the mode of formation of a wide variety of cloud forms.

Walker lived in Cambridge from 1934 until after the Second World War, officially retired but continuing to write papers on meteorological subjects. During the War he acted, in effect, as an honorary consultant on problems of long-range forecasting.

Walker was a man of wide interests, a highly proficient skater and climber in his younger days, always very fond of music, happy to spend a day out of doors sketching in water colour, ever eminently reasonable, liberal minded and very friendly. In all his posts he demonstrated his great intellectual capacity and served with distinction, deservedly reaping many honours during his long life.

CHARLES NORMAND

Mr. Stephen Butterworth, O.B.E.

STEPHEN BUTTERWORTH died on October 28 at the age of seventy-three at his home in Cowes, Isle of Wight, having retired from the Admiralty scientific staff in 1945.

After being educated at the University of Manchester, Butterworth was for eleven years a lecturer in physics at the Manchester Municipal College of Technology. Afterwards he worked for a few years on electrical standards at the National Physical Laboratory before joining the Admiralty Research Laboratory in 1921, where he remained for twenty-four years until his retirement.

Butterworth was a first-rate mathematician who possessed the rare ability to apply his mathematics successfully to a wide variety of practical problems. Before his Admiralty period he was mainly concerned with electrical investigations such as the theoretical determination of standards of inductance and accurate methods of measurement. This work, unlike much of what he did later, was fully published in the scientific Press, and his theoretical formulæ for inductances and the high-frequency resistance of coils have been extensively quoted and used.

His achievements with the Admiralty are too numerous to mention in detail, but the following indicate the diversity of his activities. In his early days he studied the possibilities of ship navigation by the use of a 'leader cable'; and, by solving the complicated electromagnetic field surrounding a submarine cable carrying alternating current, he was able to provide a complete theoretical background for all subsequent design work. He concerned himself with underwater weapons and made valuable contributions to our understanding of the stability of torpedoes which led to significant improvements in design. At another period he gave his attention to underwater explosion phenomena and among other things predicted the multiple oscillations of the explosion gas bubble, an effect that was observed experimentally many years later. In the early part of the Second World War he was much involved with the problem of the magnetic mine and made big contributions to the successful degaussing of our ships.

Butterworth possessed the ability to apply his mathematics to problems which at first sight appeared unlikely to admit of mathematical solution. He was, however, able to make progress in many cases by introducing judicious approximations to the physical conditions. Naturally, much depends on knowing the right approximations to make, and in this respect Butterworth invariably displayed an unerring understanding of the physical realities of the situation. He also showed ingenuity in devising experiments both to test his theories and to make progress with problems too complex for mathematical treatment. Naval science is often concerned with large-scale effects, where systematic and extensive experimentation is very difficult. In such cases he would aim at devising a model which could be studied exhaustively in the laboratory. He was able to show, for example, that the complicated details of magnetization of a ship's structure under the combined influence of its degaussing coils and the magnetic field of the Earth could be accurately reproduced using an appropriately scaled steel model of the ship. This made possible an enormous saving of effort when degaussing specifications had to be worked out for a variety of ships during the Second World War. In the same way, he was able to study the trajectories and the effects on entering the water of underwater projectiles by means of small models in a laboratory tank, thus reducing the need for difficult and expensive full-scale experiments at sea. In this case the technique which he developed at Teddington many years ago has been followed by other laboratories ever since.

For security reasons it was impossible for Butterworth to publish much of his work, and on this account his general recognition in the scientific world has been much less than it would otherwise have been.

Although one of the most outstanding scientists in the Admiralty's service, Butterworth was a very quiet and unassuming man. His expert advice was sought on all sides, and he was always ready to give it. His colleagues throughout the Admiralty scientific service had deep respect for him, and those young men fortunate enough to work under his direction held him almost in veneration. H. F. Willis

NEWS and VIEWS

The Queen's University, Belfast: Prof. Michael Grant, C.B.E.

Prof. Michael Grant, who holds the chair of humanity in the University of Edinburgh, has been elected president and vice-chancellor of The Queen's University, Belfast. He will succeed Sir Eric Ashby (who takes up residence as master of Clare College, Cambridge, next July) in August 1959. Prof. Grant brings a wealth of experience to his new office. He was educated at Harrow and Trinity College, Cambridge. In 1938 he was elected into a Fellowship at Trinity. During the War he was seconded from the Army as British Council representative in Turkey and he later became deputy director of the European Division of the British Council. In 1948 he was appointed professor of humanity in the University of Edinburgh, and during 1956–58 he had leave of absence from his chair to serve as first vice-chancellor of the University of Khartoum. He filled the office of vice-chancellor at Khartoum with distinction through a period of great political and constitutional unrest. Prof. Grant goes to The Queen's University at a time when it is developing rapidly. He will have the double responsibility of maintaining the University's international status and at the same time preserving the University's close ties with its region. He has high qualifications for this double responsibility, and it is a cause of great satisfaction that university education in Ulster will be under such experienced leadership.

Department of Leather Industries, University of Leeds: Prof. D. Burton

It has been announced that Prof. D. Burton is to retire in September 1959 from the chair of leather industries in the University of Leeds, which he has held since 1951. Since 1955 he has also been director of the Procter International Research Laboratory, where he was at one time the first research assistant. During his tenure of office there has been a considerable expansion of the activities of his Department. The courses have been revised and the research facilities greatly extended; an electron microscope has been installed and put to good use; the experimental tannery has been modernized and re-equipped; a laboratory for microscopy and bacteriology has been opened; and the Atkin–Thompson postgraduate research laboratory added. Among the topics studied has been the nature and material of the Dead Sea Scrolls. Prof. Burton is widely known and respected in the leather industry as well as in academic circles, and a large number of friends will wish him well in his retirement.

Prof. A. G. Ward

Mr. A. G. Ward has been appointed to succeed Prof. Burton. After obtaining first-class honours in physics at Cambridge and working, for a time, in the Department of Colloid Science in that University, Mr. Ward was lecturer in physics and mathematics at the Technical College at Stoke-on-Trent, until the Second World War, when he worked with the Armament Research Department. During 1946–49 he was in charge of research on rheology at the Building Research Station, after which he became the first director of the British Gelatine and Glue Research Association. Apart from his duties as director, Mr. Ward has made notable advances in our knowledge of the properties of gelatine. His authoritative article (with P. R. Saunders) in the recently published second volume of F. R. Eirich's "Rheology: Theory and Applications" is of outstanding merit. Though Mr. Ward's interests cover a wide field of colloid science, and his little book on colloids, published in 1945, has been much praised, he is perhaps best known as a rheologist. He was president of the British Society of Rheology during 1951–53, his term of office including the Second International Congress on Rheology held at Oxford. As president, he also served as chairman of the organizing committee of this Congress, in which capacity his administrative abilities and keen business acumen were greatly appreciated.

Molecular Biology in the University of Oregon : Dr. A. Novick

DR. AARON NOVICK, who has been on the staff of the University of Chicago for eleven years, has recently been appointed director of the Institute of Molecular Biology at the University of Oregon. He graduated in chemistry in 1940 and received the degree of Ph.D. in 1943, both in the University of Chicago. Dr. Novick's research has been principally in the genetics and physiology of micro-organisms, reaction kinetics, nuclear measurements and radiation chemistry. During 1943–47 Dr. Novick was with the Manhattan District Project, when he worked in the fields of radiation chemistry, radiochemistry and nuclear physics. In 1947 he was made a research associate with the rank of assistant professor in the Institute of Radiobiology and Biophysics of the University of Chicago. He worked as a Guggenheim Fellow at the Pasteur Institute in Paris during the year 1953–54 before returning to Chicago as associate professor.

European Organization for Nuclear Research

THE Council of the European Organization for Nuclear Research (CERN) recently approved contributions from the twelve member States totalling 55,000,000 Swiss francs for 1959 (compared with a budget of 56,000,000 Swiss francs for 1958). Good progress was made during 1958 in the construction of the Organization's two big particle accelerators and of other buildings and ancillary facilities. The first machine, a 600-MeV. synchrocyclotron, came into operation on August 1, 1957. It was recently used to demonstrate, for the first time, the two modes of decay of π-mesons—an experiment of critical importance to fundamental nuclear theory. In view of the rapid progress made at the CERN building-site during 1958, the second accelerator, the 25-GeV. proton-synchrotron, will probably be finished in 1960, the target date originally set. It will then be the biggest particle-accelerator in existence.

Prof. P. Scherrer (Switzerland) and Dr. G. Funke (Sweden) were elected as new members of the Committee of Council. Sir Harry Melville, secretary of the Department of Scientific and Industrial Research of the United Kingdom, was re-elected as member of the Committee. The following were also re-elected : M. F. de Rose (France) as president of the Council ; Prof. W. Heisenberg (German Federal Republic) and M. J. Willems (Belgium) as vice-presidents of the Council ; M. J. H. Bannier (Netherlands) as chairman of the Finance Committee ; Prof. E. Amaldi (Italy) as chairman of the Scientific Policy Committee ; and Prof. W. Heisenberg (German Federal Republic) and Prof. H. Alfvén (Sweden) as members of the Scientific Policy Committee.

Calder Hall Completed

ALL the reactors at the two Calder Hall nuclear power stations are now working. This stage was reached during the night of December 8–9 when the fourth reactor on the site went critical. The operation was successful and this reactor will now undergo a series of tests while working up to full power in preparation for linking with the grid system to provide electricity. There are two atomic stations at Calder Hall, known as 'A' and 'B'. Work on the first of these started in the summer of 1953 and on the second in 1955. Each station has two reactors and the first of the two in Calder 'A' started operating in May 1956. It achieved full power and was switched into the grid on October 17, 1956, by Her Majesty the Queen. It thus became the first atomic power station in the world to produce electricity on a commercial scale. Both the reactors on the first station have been successfully supplying electricity to the national grid system since February 1957. The power capacity of the four turbo-generators associated with the two reactors is 92 megawatts, of which about 70 megawatts is used by the grid. So far just over 750 million kilowatt hours have been supplied. The first reactor of Calder Hall 'B' started operating in March this year and has been running successfully. Delivery of power was delayed by an accident to a turbo-generator in June, but will probably take place before the end of the year. The last reactor to start operating will start production of electricity two or three months later. The two stations together will have a capacity of 184 megawatts and will supply 140 megawatts to the national grid. A similar station with four reactors is now nearing completion at Chapelcross, near Annan in Dumfriesshire. One of the reactors here is already operating and the whole station will be complete by the end of next year.

Import Duty on Scientific Apparatus and Instruments

IN a written Parliamentary reply on December 10, Sir David Eccles, president of the Board of Trade, stated that arrangements are being made for widening the scope of the arrangements for remitting duty on optical and scientific apparatus and instruments. The Board will be prepared to consider such apparatus and instruments imported on and after January 1, which satisfy the definition in the Import Duties Act, 1958, where the rate of duty is 25 per cent or more (minimum chargeable, £50). The President set out a list of apparatus and instruments which will be so considered, provided that they are not obtainable, for the time being, in the United Kingdom.

Josiah Wedgwood and Research

COMMENTING on the paragraph under this heading in *Nature* of October 25, p. 1130, Dr. A. T. Green, director of research of the British Ceramic Research Association, writes : "This is a striking example of his remarkable foresight, but I should like to point out that the letters between Wedgwood and Bentley, describing the former's efforts to persuade his fellow potters to co-operate in this venture, were rather fully extracted some 28 years ago in the "Wedgwood Bicentenary Volume" of the British Ceramic Society. The fact that Wedgwood, in 1775, proposed the formation of what might have been the first research association, has frequently been mentioned and is a matter of some pride to those of us engaged in ceramic research at the present time".

Northern Advisory Council for Further Education

THE eleventh annual report of the Northern Advisory Council for Further Education, which covers the year ended March 31, 1958, records the decision of the Minister of Education to develop the Rutherford College of Technology into a college of advanced technology (see *Nature*, **179**, 1277; 1957), and the Committee of Chief Education Officers has already submitted recommendations on advanced courses. Among the new buildings noted in this report are the second instalment of Carlisle Technical College, to be ready for occupation for the session 1959–60; completion of the first phase of additions to the Workington College of Further Education: full completion of the Joint Stockton/Billingham Technical College; completion of the first instalment of the Durham Technical College and the Bishop Auckland Technical College; commencement of the third stage of the new Rutherford College of Technology; and the coming into use of the first instalment of Easington Technical College; the first instalments of the County Technical College, Ashington, and the South Shields Marine and Technical College; and of major extensions to the Sunderland College of Art. After a general review of the Willis Jackson report on the "Supply and Training of Teachers for Technical Colleges", the programme committee recommended that the Advisory Council should take appropriate steps to implement the recommendation that industry should be more fully acquainted with the staffing problems of colleges; that through the programme committee it should prepare a comprehensive programme of part-time courses of training for technical teachers, and that a proper service of organizing tutors should be established. The first series of short initial training courses for new teachers in technical colleges was held at Middlesbrough, Newcastle and Workington.

The International Institute for the Conservation of Museum Objects

The International Institute for the Conservation of Museum Objects was founded to provide a permanent organization to co-ordinate and improve the knowledge, methods and working standards needed to protect and preserve precious material of all kinds. Dissemination of information on research into and development of all processes connected with conservation, both scientific and technical, is an essential part of its function. A substantial grant from the Gulbenkian Foundation, covering the next three years, has recently been received by the Institute. Since 1950 the Institute has expanded continuously, until now it has members in more than thirty countries and in most major museums of the world. It has published its journal, *Studies in Conservation*, which carries out the Institute's policy of disseminating information, since October 1952 (hitherto published twice yearly, but quarterly beginning 1959), and *Abstracts of the Technical Literature on Archaeology and the Fine Arts* since 1955. Members are kept in touch with each other by means of the *News Letter*, which also carries items of special interest, and which has been published by the American Office of the Institute since 1952. One of the most important functions of the Institute is to be able to put members in touch with the appropriate experts in any particular field of conservation. This is a service which is constantly expanding, and although up to the present time it has been available to members only, it is hoped to be able to extend the service to the general public in 1959. The Institute, while not possessing a laboratory of its own, is in touch with all institutions which specialize in technical research and development relating to the care of artistic patrimony, and has become one of the internationally recognized channels for the communication of their results.

In order to increase the international character of the Institute, the former Management Committee retired in January 1958, and was replaced by a ten-member Council, representing approximately the present topographical distribution of members of the Institute. Its members are: *President*, W. G. Constable; *Vice-Presidents*, Dr. P. B. Coremans, Dr. H. J. Plenderleith, F. I. G. Rawlins; *Secretary-General*, N. S. Brommelle; *Treasurer*, S. Rees Jones; *Ordinary Members of Council*, R. J. Gettens, Dr. S. Paramasivan, Dr. A. van Schendel, G. L. Stout; *Membership Committee*, Dr. Paul Coremans, Sheldon Keck, Dr. Arthur van Schendel, Mme. Magdeleine Hours, the Secretary-General (*ex-officio*). Information concerning the Institute can be obtained from the assistant secretary, Miss R. M. Spielman, c/o The National Gallery, Trafalgar Square, London, W.C.2.

Electric Technology, U.S.S.R.

The increasing importance of Russian scientific and technical literature is reflected in the appearance of journals comprising selected papers and articles translated from the Russian. A recent addition to this series is *Electric Technology, U.S.S.R.* (four volumes comprising approximately 700 pages per annum. Annual subscription £20 (56 dollars); single volumes £6 (17 dollars). London and New York: Pergamon Press, 1958), containing translations of articles from *Elektrichestvo*, the leading Russian journal dealing with heavy-current electrical engineering and, incidentally, one of the oldest electrical journals in the world. It is proposed to publish in the new journal only those articles from *Elektrichestvo* having the greatest general interest and value. The publishers state, however, that they will be able to provide a translation of any article which has appeared in the Russian journal. The contents of the first issue represent papers selected from *Elektrichestvo*, Nos. 1–4, 1957, and cover a wide range of topics, including, for example, short-circuit transients on long lines, the problem of impulse tests on the turn insulation of a high-voltage machine, the use of amplidyne and transistor amplifiers in industrial drives, the measurement of earth resistances and the stabilities of measuring instruments using 'Magnico' and 'Alnico'.

While it is no doubt true that the existing abstracting, translating and reprint services cover the field of Russian scientific literature very satisfactorily and provide the scientist and engineer with copies of specific papers which he may wish to consult, there does appear to be a useful purpose to be served by a journal which selects, translates and publishes at intervals the most important Russian articles in a given field. Such a publication enables the reader not only to form some picture of the range of work being done in his field but also to read, from time to time, an important paper in full, without requiring to take special steps to obtain it in translation. *Electric Technology, U.S.S.R.*, is a welcome addition to the literature of electrical engineering.

International Glossary of Wood Anatomy

It is very satisfactory to find that action is being taken in several scientific fields to secure agreement on the precise meaning of the many special terms that have come into use among research workers and others. Relatively few such terms have been deliberately invented and defined on introduction into the literature, and even of these a large proportion tend, with time, to be loosely used, sometimes with a meaning very different from what was originally intended. In this way, ambiguity creeps in, causing confusion until action is taken to secure standardization, or at least definition, and indication of preferred usage. Among the groups to take action of this kind is the International Association of Wood Anatomists which, realizing the need for revision of the glossary produced in 1933, has recently published a new glossary of more than two hundred terms with definitions (*Tropical Woods*, No. 107; October 1957: International Glossary of Terms used in Wood Anatomy. Pp. 36. Zurich: International Association of Wood Anatomists, Universitätstrasse 2; New Haven, Conn.: Prof. William L. Stern, 205 Prospect Street, 1957). By a fortunate coincidence, the second part of a British Commonwealth Forest Terminology was under compilation at the same time and agreement has been secured for all the terms included in both. Furthermore, it has been agreed that these English glossaries, co-ordinated so far as possible with the American equivalents, are to form the basis of multi-lingual glossaries for international usage. This is an important step in the right direction.

Gairdner Foundation Awards in Arthritis and Heart Disease

THE Gairdner Foundation has announced its first international awards in arthritis and heart disease, totalling 40,000 dollars. Medical scientists from Britain, the United States and Canada are included among the seven recipients. The Gairdner Foundation Award of Merit of 25,000 dollars has been awarded jointly to Dr. Alfred Blalock and Dr. Helen B. Taussig (Johns Hopkins University, Baltimore) for their initial development of what is popularly known as the 'blue-baby operation' for congenital obstruction of the pulmonary artery. Three annual awards of 5,000 dollars each have been awarded to the following: Profs. H. M. Rose and C. Ragan (Columbia University, New York) for their discovery of an agglutinating reaction affording the first practical laboratory blood-test for the diagnosis of rheumatoid arthritis; to Prof. W. D. M. Paton (Royal College of Surgeons of England) and Prof. Eleanor Zaimis (Royal Free Hospital School of Medicine, London) for their discovery of the methonium compounds, the first drugs effective in the treatment of high blood pressure; to Dr. W. G. Bigelow (University of Toronto) for his development of the technique of hypothermia for heart surgery.

Christmas Lectures at the Science Museum

CHRISTMAS lectures for children aged thirteen to seventeen years are to be given for the first time this year at the Science Museum. There will be two subjects: first, "From Man Power to Atomic Power" on December 31, repeated on January 1 and 2; second, "The Story of Flight" on January 5, repeated on January 6 and 7. The lectures will be illustrated by many demonstrations and the young audiences will be able to see such things as a Montgolfier hot-air balloon rising to the ceiling of the lecture theatre and a noisy and spectacular 'mock-up' of a gas turbine. The lectures will commence at 2.30 p.m. and admission is free and without ticket.

Science Museum Exhibition on Controlled Nuclear Fusion

A SMALL exhibition at the Science Museum, South Kensington, open from December 18 until the end of March 1959, illustrates British research in the field of controlled nuclear fusion. The centre-piece of the exhibition is a one-third scale model of Zeta, the apparatus developed at Harwell. This model was shown in the exhibition held at Geneva last September in connexion with the Second International Conference on the Peaceful Uses of Atomic Energy, and simulates the flashing discharge which in Zeta produces fusion of atoms. Another scale model, which was on view for six months at the Brussels World Fair, shows the apparatus known as Sceptre III, which was made by Associated Electrical Industries, Ltd., and gives results similar to those obtained with Zeta. Examples are also shown of pioneer apparatus used at the beginning of this type of work twelve years ago.

Announcements

THE Agricultural University of Wageningen is organizing an international conference on "Enzymes and their Action", to be held at Wageningen during April 6–10. Further information can be obtained from Dr. H. Veldkamp, Laboratorium voor Microbiologie, Hesselink van Suchtelenweg 4, Wageningen, The Netherlands.

AN international conference on "Co-ordination Chemistry", under the sponsorship of the International Union of Pure and Applied Chemistry, will be held in London during April 6–11. The conference is being organized by the Chemical Society, and further information can be obtained from the Secretary, International Conference on Co-ordination Chemistry, Chemical Society, Burlington House, London, W.1.

A SYMPOSIUM on "The Biology of Weeds" is being arranged by the British Ecological Society, to be held in Oxford during April 2–4. The programme will include papers on the ecology, systematics and physiology of weeds, the origin and development of weed floras, competition and population studies in weeds, and dormancy characteristics of weed species. Limited accommodation will be provided in Brasenose College. Inquiries should be addressed to Dr. J. L. Harper, Department of Agriculture, University of Oxford.

THE Institute of Physics is arranging a conference on "Some Aspects of Magnetism", to be held in Sheffield during September 22–24, 1959. The subjects to be covered by the conference are: (*a*) fundamental theories of ferro-, ferri- and antiferro-magnetism, including magnetic structure; (*b*) theories of technical magnetization processes, including hysteresis, coercivity, anisotropy and directional effects; (*c*) domain phenomena in bulk materials and thin films; (*d*) antiferromagnetism in metals and non-metals. Each session will be opened by an invited speaker, and other contributions should be submitted to the Conference Secretary, Institute of Physics, 47 Belgrave Square, London, S.W.1, before January 31. Abstracts (but not preprints) will be circulated before the conference, the proceedings of which will not be published in full.

REORGANIZATION OF THE METEOROLOGICAL OFFICE

IN 1955 a small committee with Lord Brabazon as chairman was appointed by the Secretary of State for Air to review the organization of the Meteorological Office. The quite radical changes that followed the investigations and recommendations of the Brabazon Committee took effect on July 1, 1957, and their nature is described in the annual report of the Meteorological Office*.

It was as a department of the Board of Trade, serving the interests of shipping, that the Meteorological Service began its existence in 1855, and it assumed the name by which it is now known when it was later transferred to the control of a committee nominated by the Royal Society. The Office retained its autonomy as a separate Government department through several succeeding reorganizations, until, in 1919, the War Cabinet decreed that it should absorb the three separate meteorological units which had been established to serve the needs of the Royal Navy, the Army and the Royal Air Force, and that it should henceforth become attached to the department making the greatest use of its services, the Air Ministry. A Meteorological Committee composed of representatives of its principal customers, of the Royal Societies of London and Edinburgh, and of the universities, was set up to act as a board of management.

During the period between the two World Wars, the comparatively small scientific staff was, in the main, fully occupied in operational forecasting, which inevitably involved liability for work at irregular hours and frequent transfers between stations at home and abroad, many in isolated situations. Less-favourable conditions for research can scarcely be imagined, yet some members of the staff successfully undertook investigations of fundamental importance, mostly in their leisure hours.

During the Second World War, the director, the late Sir Nelson Johnson, instigated two important developments with the aim of furthering the progress of research within the Office. The Meteorological Research Committee, composed of senior scientists from within the service and from the universities, was established in 1941 with the object of providing advice on the general planning of the programme of research. During the next year the Meteorological Research Flight was set up at Farnborough and has now behind it a substantial achievement that has earned an international reputation.

It was probably the difficulty experienced after the War in securing adequate staff with the necessary qualifications that was the principal reason for the appointment of the Brabazon Committee, a year after Sir Graham Sutton had assumed the post of director. (The full report of the Brabazon Committee has not been published.) The difficulty of recruitment was partly due to the irregular hours of duty that must be served by the practising meteorologist and partly to the remote situation of many stations. Besides, there are few appointments for the trained meteorologist outside the Office, and it was common knowledge that opportunities for promotion to senior posts compared unfavourably with those in most other branches of the Scientific Civil Service. The reorganization that has now taken place will do much to remedy this state of affairs. New posts have been created in the highest grades of both the scientific and experimental officer classes and the total number of posts in the scientific officer class (145 at present) has been slightly reduced to ensure that all entrants in this class will have an expectation of reaching at least the rank of senior principal scientific officer within a reasonable period.

The further recommendations of the Brabazon Committee that have been promulgated in the annual report reveal that the scope of the Committee's survey has been wide. The continued progress and the high standing as a scientific institution acquired while the Office has been under the Air Ministry are taken to indicate that the Meteorological Office is in its right place in the Government organization. The post of director is raised to that of director-general, and there are now two directors in the grade of chief scientific officer, Dr. J. M. Stagg and Dr. R. C. Sutcliffe, responsible for services and research, respectively. In addition, there is a third section for administrative and general duties, headed by an assistant secretary, to be known as secretary to the Meteorological Office, a change which will presumably relieve the senior scientists of considerable administrative duties and at the same time make the Office a more self-contained unit.

The Meteorological Committee, established in 1919, is deemed to be too large and has been replaced by an Advisory Committee of "not more than five members, all outside Government service". Its functions are "to keep under review the progress and efficiency of the Meteorological Office and the broad lines of its current and future policy as well as the general scale of effort and expenditure". Its first chairman is Lord Hurcomb, and the members are Sir Austin Anderson, Sir David Brunt, Sir Charles Normand (*ex-officio* as chairman of the Meteorological Research Committee, which is to continue unaltered) and Col. Stopford Sackville.

The plans for improved facilities for research are imposing. Already, during the past decade, a steadily increasing series of papers, impressive both in quality and quantity, has come before the Meteorological Research Committee. This has been made possible by assigning many forecasting duties to experimental officers, so permitting the allocation of research tasks to the scientific officers, freed from operational work at out-stations. The tendency for delay in the practical application of the results of research is recognized by the appointment of a new assistant director, who will not only keep the forecasters acquainted with the progress of research that may be valuable to them but will also formulate, for presentation to the researchers, new problems that arise from the experience of the forecasters.

There appears, however, to have been no examination of the somewhat anomalous position of the three British magnetic observatories. Two of these, at Lerwick and Eskdalemuir, are administered and staffed by the Meteorological Office, the third at Hartland Point (previously at Abinger) by the Royal Greenwich Observatory. The staff who have been posted to the Meteorological Office observatories have had to divide their allegiance between the almost unrelated sciences of meteorology and geomagnetism, for no senior post has been attached to the latter. Nevertheless, this association of geomagnetism with the Meteorological Office has been not unsuccessful, for the traditions established by Chree have been well maintained by Goldie, Stagg, and more recently, McIntosh and Lewis. Yet there is surely a strong case for the establishment of at least one senior observatory post so that a man of proved ability in geomagnetic studies, who wishes to devote himself to such work, may do so without sacrificing his prospects of promotion.

---

* Annual Report on the Meteorological Office for the year April 1, 1957, to March 31, 1958. Pp. 52+4 plates. (M.O. 650.) (London: H.M. Stationery Office, 1958.) 3s. 6d. net.

The annual report begins with a summary by the Director-General of the changes as they affect the Meteorological Office as a public service and scientific institution. In this, Sir Graham Sutton points out that the advantages of the reorganization will be fully realized only when the staff at present at Victory House, Harrow, Dunstable and the Training School at Stanmore move together to occupy the new buildings, now being erected at Bracknell and likely to be completed in 1961. There follows a detailed account by the Director of Services of the responsibilities of his directorate, which includes not only general forecasting for a wide range of customers, but also the complex organization of communications, the observations, both surface and upper air, on land and at sea, the climatological services, agricultural meteorology and training. The Director of Research summarizes the various problems now under investigation and discusses the work of instrument development, which is also his responsibility. Research on numerical forecasting, involving the development of techniques for predicting the pressure distribution by calculations from the dynamical and physical equations by means of an electronic computer, is being actively pursued. This very readable report concludes with two short chapters on international co-operation and administration.

With the recent rapid development of techniques for the measurement of the physical structure of the atmosphere to great altitudes and their wide use throughout the world during the International Geophysical Year, the mass of new data which is becoming available will make possible the investigation of many fundamental problems in meteorology that were hitherto intractable. The quite excellent facilities for this research which are now provided in the Meteorological Office have therefore been achieved at an opportune time, and it can be confidently anticipated that the national service will play an increasingly important part in advancing the science of meteorology.

J. PATON

SUPPLY AND DISTRIBUTION OF CHEMICAL ENGINEERS IN BRITAIN

THE Institution of Chemical Engineers, ever since its inception thirty-five years ago, has pressed for an appreciation of the importance of chemical engineering in the national economy and has made unceasing efforts to promote the training of chemical engineers; but development in Britain lagged far behind that in the United States, and it was not until the beginning of the Second World War, when the University of London was persuaded to institute a degree in chemical engineering, that the profession was generally recognized as a separate discipline. From that time progress was more rapid, and in recent years, following the national awakening to the importance of professional engineers and the multiplication of training courses, the number of chemical engineers has increased still more rapidly. The increase would have been greater still but for one factor, long foreseen by the profession—the ever-growing difficulty of obtaining qualified teachers. A state had been reached in which a promising graduate, immediately on leaving the university, could secure a higher salary in industry than some of those who had taught him. It was consequently not surprising that there were few candidates for teaching posts.

Earlier this year the Institution published a survey of output of chemical engineers in Great Britain, from which it was concluded that by 1966, provided the situation as regards teaching staff did not become worse, the yearly output might be about 950, as against a requirement of at least 1,100 (see *Nature*, 181, 1382; 1958). This would be an improvement on the present position but would still leave a shortage. Statistical information on this subject is scanty and the Institution has recently circularized its qualified members in order to ascertain where they work, in what industry and what position they hold. Salaries, unfortunately, have been omitted. 79 per cent made returns and it was hoped that these might indicate a special shortage of chemical engineers either in certain regions, industries or occupations. The results are interesting, but difficult to interpret; for example, the number of chemical engineers in a given region depends mainly upon the number of factories of a type employing a high proportion of chemical engineers (for example, oil refineries) which happen to be located in that region. It also depends on the prospects which the new recruit considers that these factories offer and on the amenities of the district. A low figure for any region does not necessarily indicate that many more chemical engineers are required there.

The returns showing the occupation of members are more illuminating, as they can be compared with similar figures for 1953. In that year, about 20 per cent were engaged in each of four main branches: (1) administration and management; (2) plant operation and maintenance; (3) design and construction; and (4) research and development. In 1957, no less than 30 per cent were occupied in administration; a remarkable increase, due, perhaps, to the multiplicity of subjects, not all purely technical, which chemical engineers have to study and the wide outlook which results. This increase is offset by a reduction from 22·8 to 12·3 per cent in the numbers engaged in the operation and maintenance of chemical plant, and is a welcome sign since it not only indicates the advancement of automatic control but also a diminution of the employment of graduates in duties which could be carried out equally well by those with lower qualifications. It is surprising to find that corresponding figures for two of these major branches in the United States differ considerably, being 31 per cent for research and development compared with 23 per cent in Britain, but only 7 per cent for design and construction against 21 per cent, a possible explanation being that development may be carried further in the United States and may include much which is classed as design in Britain. Among the minor occupations, teaching shows a gratifying increase from 3·0 to 5·1 per cent, the present number of teachers being more than 100, but this is still not enough.

The total number of qualified members of the Institution in 1957 was 2,176, a figure considerably higher than that given in the Government report on Scientific and Engineering Manpower in 1956. The distribution of these members among thirty-three different industries and occupations is shown and also the number of chemical engineers per 1,000 males employed. As might be expected, the mineral-oil refining industry, which may be regarded as the cradle of chemical engineering, heads the list with 7·3 chemical engineers per 1,000 employed, and it may also be noted that it was calculated some years ago that the value of the product per man-hour in the oil industry was far higher than in any other heavy manufacturing industry. Oil refining seems to be approaching a state in which the only labour required will be for the erection and maintenance of plant, operation being entirely automatic, and its chemical engineers are employed in research, design, development and management. It would, however, be unwise to conclude from this that the efficiency of an industry is directly related to the number of chemical engineers employed. The iron and steel manufacturing industry, in which many chemical engineering processes are involved, employs only twenty chemical engineers, or 0·05 per 1,000 males, and is at the bottom of the list. It is true that automatic operation has not been adopted in this industry to the same extent as in the case of oil, but this is doubtless because it would be more complicated and difficult to install, and would probably be uneconomic. There is certainly no question of the iron and steel industry being inefficient, but there is a possibility that it does not recognize fully the potentialities of the chemical engineer, and that many of the highly qualified staff who are, in effect, doing chemical engineering work were recruited as metallurgists or mechanical engineers. This example may show the difficulty of interpreting employment statistics.

Of the other items in the list of industries, one is deserving of particular attention, namely, atomic energy. This has already secured the services of more than one hundred chemical engineers, and it seems certain that the number required in the near future will be very large.

All the figures now published will have their real value in the future. It is to be hoped that a similar set will be published in about five years time, and it may then be possible to make reliable predictions. Even now, it may be regarded as a practical certainty that there will be no over-production of chemical engineers in the coming quinquennium.

H. E. WATSON

FUEL AND POWER IN BRITISH INDUSTRY

It is abundantly clear that the supply of suitable fuels and the provision of adequate power represent essential factors in any efficient industrial unit. It may well be doubted, however, whether, in view of the ever-increasing complexity of the situation, those responsible for important industrial decisions are always in a position to appreciate thoroughly all the technological and commercial factors involved. It was in the hope of doing something to assist in the planning of such development, so far as the supply of fuel and power is concerned, that the Manchester Joint Research Council arranged a symposium during November 5–7, which was held at the Manchester College of Science and Technology. A very large amount of material has been published on these matters from the technological point of view, and it was not the intention of the Council in organizing the symposium to duplicate this, the general theme of the meeting being the interaction between technological advances and their economic consequences.

The meeting was opened by Lord Mills, Minister of Power, who summed up the Government's policy as permitting the consumer to decide from his own experience what is required to meet his own particular needs, coupled with the provision of expert advice, where this is required. It has been estimated that by 1965 the total fuel consumption of the United Kingdom will have risen to about 300 million tons of 'coal-equivalent' a year and to 350 million tons by 1975. A marked change in the pattern of the fuel and power used is to be expected; there will probably be a continued switch from the direct use of raw coal to its application in the more refined forms of gas and electricity and an increase in the use of oil, due to the continued expansion of road transport, the re-equipment of the railways, the continuance of recent trends in domestic heating and the change from solid fuel to oil in those industrial and commercial uses where it has special attractions.

This greater refinement means heavy capital investments but offers great savings both in operating and fuel costs, and, in addition, there is a marked reduction in the atmospheric pollution associated with the use of solid fuel.

It is often argued, the Minister said, that the Government should direct the fuel to be used for specific purposes. In reply to this he added: "We should certainly hesitate to adopt such a policy of Government direction on fuel use for two main reasons. In the first place, the detailed policy of control could not really work; there is so much uncertainty regarding the best fuel to employ in particular conditions and, secondly, if there is one thing which central control lacks it is flexibility. A pattern laid down as appropriate at a particular time might quickly become obsolete and uneconomic". It is important, too, in his view, that the importation of oil should be in the crude form, from an increasing variety of sources and processed at refineries in the United Kingdom.

So far as nuclear power is concerned, there would be a rapid expansion to some 5,000–6,000 megawatts in 1966, and thereafter continued expansion may prove economic. Concerning the use of small coal, this should become progressively a more attractive purchase, and it is the duty of all forms of industry, nationalized or otherwise, to switch their demands so far as possible from larger sizes to small coal.

The remainder of the meeting was devoted to the industrial consideration of oil, coal, gas, electricity and nuclear energy. The lectures on oil were given by Dr. P. H. Frankel, of Petroleum Economics Ltd., who dealt with the economic aspect, and Mr. W. S. Ault and Mr. H. Cunliffe, both of Shell-Mex and B.P. Ltd., who were concerned with the uses. Dr. Frankel, in a most valuable and provocative paper, suggested that with the expansion of existing oil-fields and the opening of new ones—the Sahara was mentioned in particular—there would appear to be abundant reserves on a world scale. Great Britain, however, is especially subject to political vicissitudes, and he therefore stressed the need for a balanced fuel economy. In the past few years vast new oil fields have been found, the exploitation of which, now that they have been located, should be relatively cheap. This oil will tend to press on the existing markets, and he assumed, therefore, that the price of liquid fuel would tend to fall. A question which he posed to the Conference was whether it is more economic for Great Britain to go to the limit of marginal high-cost production of coal with investment on a commensurate scale, or to substitute oil for, say, the last 10 per cent of our requirements. He pointed out that Western Europe is dependent on sea-borne oil, but he believes that there are plenty of tankers available, while pipe-lines based on Marseilles, Rotterdam and Hamburg would facilitate distribution.

Mr. Ault and Mr. Cunliffe's paper on the uses of oil, after stressing its importance in all forms of transport, passed on to consider its use in general industry. Although electrical energy can be produced from coal at the generating station at the lowest cost, there are even here special cases in which oil-firing is worthy of consideration. The efficiency of combined generation of electricity and recovery of waste heat, using either Diesel or gas turbine or both, was given as 80 per cent. The storage space required for oil fuel is much lower than that needed for coal, and oil firing offers further advantages in mechanical equipment, labour costs, convenience and automatic control. Furnaces may be heated by a wide variety of fuels, ranging from propane to heavy fuel oils, and in such processes as steel-making the high radiation from the flame leads to more rapid melting. The question of atmospheric contamination by sulphur was mentioned, though in subsequent discussion it was not clear that, from this point of view, oil is markedly superior to coal. It does, however, possess marked advantages in the absence of grit turned into the air.

In his review of Britain's resources of coal, and considering seams not less than 1 ft. thick and not more than 4,000 ft. deep, Mr. A. M. Wandless (National Coal Board) estimated that these are of the order of 1,000 million tons which can be economically worked. He stressed the fact that it is not the mere quantity available but the 'rank', of which the coals proved cover a range unique in Western Europe. With the increase of mechanization the increased costs of production are not likely to go on rising unchecked. This cost of production varies inversely with the rank, of which the various industrial uses extend over a wide range, and low rank does not necessarily imply low quality. The present output of the various types of coal is not seriously out of phase with the resources of Britain, though a slow decline in quality must be expected. About half the output is of low rank, and it is for the technician to ensure that the use of such coal should be as great as possible.

One of the most important contributions was that of Mr. D. Hicks (National Coal Board), on "Coal Utilization". Although the total mineral resources of Britain are limited in type, they are not insignificant in quantity. There is, for example, enough economically accessible coal to sustain a high national productivity for more than a hundred years. It would seem wise to ensure that these natural advantages are not used carelessly, and that we do not become increasingly dependent on external resources, with all the uncertainties and risks, political and economical, that this implies.

From the commencement of the industrial revolution there has been a fairly direct relationship between national income and the consumption of primary fuels, and estimates of the future demands of fuel and power have been based within fairly wide confidence limits on an extrapolation of this relationship. In industry the maximum utilization of time and resources has not yet been achieved, and big improvements in productivity are possible with a smaller expenditure of mechanical energy than extrapolation from past performance would suggest. Mr. Hicks recognized that we cannot sustain a high industrial output in Britain wholly on our internal resources; neither can we support our economy without importing some oil, particularly for our air and road transport systems, for lubrication and for certain chemical feed stocks. He asked, however, whether it is not a matter for serious consideration whether we should become increasingly dependent for heating and for power generation on imported fuel. In pleading for an increased efficiency in the use of fuels of all kinds, Mr. Hicks pointed out that it is too facile to assume that merely by switching from one fuel to another an automatic improvement in efficiency will result. All fuels, both primary and secondary, require close attention to the choice of equipment and to the operation. It is far less costly, ton for ton, and takes far less time to save coal than to create a new pit.

In his lecture on "Gas", Sir Harold Smith (of the Gas Council) emphasized that the industry is passing through a period of change, perhaps the most important in its whole history. It is facing two new challenges, one due to the increasing shortage of suitable fuel and the other from nuclear power, and is meeting these challenges by basic experiments from which a new gas industry may be developed. New types of coal and new materials are being investigated, and in particular the high-pressure–high-temperature gasification of small, low-quality coal. The collection and distribution of methane from mines and from catalytic plants should make a further useful addition to the supplies available, and he particularly emphasized the interest being taken in the importation of liquid natural gas from America. A thirty-thousand ton tanker would be capable of carrying the equivalent of two million tons of coal. Gas has advantages as an industrial fuel due to its ease of control and the very wide range of temperature which can be obtained.

In the discussion, Mr. D. P. Welman (North Western Gas Board) envisaged the transformation of the existing industry into a truly chemical one, and mentioned the experiments of the North West Gas Board in the development of the hydrogenation process which, if as successful as appears probable at the moment, may well revolutionize the whole industry. The preliminary work will take some four to five years, and a further three or four years will be required to construct a large-scale plant. He concluded by claiming that the gas industry uses coal more efficiently than any other major industry does.

"Nuclear Power" was discussed by Mr. P. T. Fletcher (United Kingdom Atomic Energy Authority). Broadly speaking, the capital cost of the present plant is three times that of a conventional coal-fired generating station. The fuel costs, however, are about a half, so that there is not very much to choose for base load operation between the cost of power generated in the two ways. If, however, the bigger and more advanced stations which are envisaged materialize, the cost per unit of electricity generated from nuclear energy may fall as low as 0·4*d*. per unit. A point of great importance in connexion with nuclear power stations is the load factor, which is more important than with coal. So far as the gas-cooled reactor is concerned, the three main lines of development are an increase in the temperature of the gas leaving the reactor, the design of the fuel elements so that heat is transferred to the gas more effectively—thin rods stacked in clusters in uranium oxide were suggested in this connexion—and reduction in capital cost by simplification of lay-out. Considerable interest was expressed in the future of the boiling-water reactor using enriched uranium or plutonium as the fuel, a system which, it was suggested, would result in marked reductions in the initial capital cost. Mr. Fletcher expressed the opinion that it is justifiable to spend £40–£50 million on experimental work when the potential saving might exceed £200 million. The cost of a prototype plant from the initial laboratory stage is of the order of £20 million, and he believed, therefore, that two such prototypes may justifiably be designed. In the discussion, Mr. M. Zvegintzov (National Research Development Corporation) stated that about twelve times as much money is being put into research in connexion with atomic energy as into all other fuel projects, and asked what the coal or gas industries could do if they had the £50 million for development purposes which Mr. Fletcher suggested for nuclear power. It is still, in Mr. Fletcher's view, very difficult to predict the next stage of development, and even the present programme of research and development will take many years to complete. He was sure, however, that the present United Kingdom pattern of nuclear development was justifiable both economically and technically.

The lectures on "Electricity", by Mr. T. E. Daniel and Mr. A. O. Johnson, were devoted, in the main, to a consideration of its use in electro-heating. It was pointed out that the consumption doubles every ten years, and the view was expressed that the future trend of price should tend increasingly to favour electric energy. The largest single user in Britain is the steel industry, but it was suggested that electrical heating would eventually displace fuel-fired furnaces both for the melting and annealing of glass, and in the ceramic and refractory industries. Advantages of electric heating are its flexibility, the possibility of thermal storage, so far as space heating is concerned, and the extent to which, by adequate instrumentation, its utilization could be rendered automatic. In modern conventional power stations an efficiency of 35 per cent can be obtained, and by a marked increase in size 37–38 per cent would not be unreasonable. Both in the lecture and discussion the possibility of extended use of the heat pump was mentioned, which, in the view of Mr. Frank Rostron (Ferranti Ltd.), has great possibilities when it can be built into the structure.

The final session was devoted to a general discussion with particular reference to future trends. Mr. G. A. J. Begg (Imperial Chemical Industries Ltd.) dealt with the chemical industry and gave figures illustrating the marked economies which have been achieved during the past forty years ; despite these figures, the curve has not yet become asymptotic and further economies may reasonably be expected. Much depends on the elimination of heat losses by the use of waste-heat boilers and in general the recovery of low-grade heat. The siting of factories in relation to generating stations is an important point, as is the private generation of electricity in industry. the three such main producers being the chemical industry itself, the iron and steel industry and paper-making. In small plants oil has great advantages, but throughout capital cost is a basic factor.

The metallurgical industries were discussed by Dr. T. P. Colclough (British Iron and Steel Federation), who pointed out the astonishing economies in fuel which have been achieved in the past thirty years. In 1927, the consumption amounted to 55 cwt. per ton of finished steel ; this had been reduced in 1957 to 28·5. Sintering, the recovery of waste heat, the effective use of blast furnace and coke-oven gas and oil firing have been the major reasons for this. The use of oxygen in the open-hearth furnace to increase the rate of combustion and therefore of refinement is a comparatively new technique, which may well have very marked future influence. In this connexion there is a vast new field in the pneumatic (Bessemer) processes which, with tonnage oxygen available, are opening up a new era.

The trends in general industry were discussed by Dr. W. A. Macfarlane (National Industrial Fuel Efficiency Service), who said that in the past ten years the increase in the energy used in Britain in general industry has been about 40 per cent, and attention was directed to the relatively enormous economies which could be effected by more careful attention to the factors leading to increased efficiency. He believed that 20 per cent of the fuel used could thus be saved.

One may, in conclusion, quote some words of Sir Raymond Street, spoken at the conclusion of a series of meetings on "Science and Industry", arranged by the Manchester Chamber of Commerce in 1944, to which Mr. Hicks made reference : "If you came to this meeting hoping to have a simple answer served up on a platter, you will be disappointed. You have to wrestle with this matter each for himself. Heavy reading, hard study, anxious thought, persistent inquiry, costly experimentation—these are unavoidable and you will drop behind if you cannot stand the pace. It is going to be a difficult, testing life after the war, but full of interest and reward for those that can take it". It is now more than fourteen years since these words were spoken, but they still apply, and particularly so in respect of the problems of fuel and power.

F. C. Thompson

THE LIBRARY ASSOCIATION

CONFERENCE AT BRIGHTON

THE papers presented at the annual conference of the Library Association at Brighton during September 23–26 ranged over a wide field, but the two of most direct interest to the scientist are those in which Mr. W. L. A. Saunders, deputy-librarian, University of Sheffield, discussed current problems of university libraries, and Mr. C. H. Wright, county technical librarian, Hertfordshire, those of special libraries.

Prof. Raymond Irwin in his presidential address reviewing the work and technique of librarianship, including committee work and the place and value of conferences, insisted that librarianship was all directly and closely connected with books and their proper use. The librarian's first responsibility was to help others to read or to find information. His second responsibility was to read himself: to read intelligently, systematically; widely but not aimlessly; with understanding, with sympathy and with appreciation. No routine should be tolerated which hindered rather than helped the discharge of these responsibilities, and Prof. Irwin urged an honest and unprejudiced review of all routines. Books, he insisted, were never more alive than to-day: there was no substitute for the book and there never would be. Finally, insisting on the importance of the librarian himself and the limitations of administrative and bibliographic techniques, Prof. Irwin said that British librarians and librarianship were to-day being exported to Australia, Africa, the Middle East, Canada, the Caribbean and the United States, but there was grave need to increase the export of British books, particularly scientific and technical books, to many parts of the world besides Pakistan. With these books must go British ideas about books and about librarianship, and he hoped we would continue to send out both British librarians and British-trained librarians.

Mr. Saunders said that the main problem facing universities and university librarians at present arises from the increase in the student population, from 50,000 in 1939 to 90,000 at present, with at least 124,000 expected by 1965. At Sheffield it had risen from 767 in 1939 to about 2,000 in 1952, and early this year a target of 4,500 was set. The increase had already set a severe strain on storage space and seating accommodation in many libraries, and the latter was aggravated by the fact that a relatively small proportion of students lived in halls of residence. Few university libraries held excessively large collections, but several were near the 400,000 and 500,000 marks, and in twenty or thirty years many provincial university libraries were likely to approach a million volumes. Collections of this order could daunt new students, and the problem of providing an adequate introduction for an annual intake of several hundred students was serious. In addition to an introductory tour, Mr. Saunders suggested that all undergraduates should at least be made aware of the bibliographical tools of their own field. The whole question of departmental libraries required objective review, and finally he stressed the importance of providing a reasonable salary scale for non-graduate staff so as to attract those capable of relieving the graduate staff of work which did not require high academic qualifications.

Mr. C. H. Wright, pointing out that the special library in the past was chiefly concerned with the flow of information, whereas the public and university libraries were concerned with the flow of books, said that with the vast expansion of scientific and technical literature, the mechanics of organizing the flow of information had become as important to the special librarian as the degree of subject knowledge, while the increasing demand for scientific, technical and commercial information had made the public librarian more aware of the value of specialized subject knowledge. There was thus a better understanding of what are the common foundations of librarianship. After reviewing the problems of staffing a special library and suggesting that more attention should be given to the question of providing suitable training, Mr. Wright said that the present national system of co-operative loan service did not meet all the day-to-day requirements of the industrial or commercial library, and while the National Lending Library for Science and Technology might solve many problems, it appeared likely to be many years before its service could be put to the test. All the investigations made had illustrated the need for local information services and liaison between all the parties concerned. Local schemes of co-operation, however, required a few paid servants to implement policy if co-operation was to be effective. Mr. Wright thought that it was a pity that, in spite of its vital interest in the free flow of information, the Department of Scientific and Industrial Research should be unable to offer financial support to areas where librarians were anxious to co-operate but unable to provide the necessary staff. Such support should be conditional on industry and local authorities continuing to provide an adequate flow of scientific and technical literature. Finally, he referred to the opportunity for a co-operative research organization capable of producing more efficient microtext readers, information retrieval units, and simple photocopying apparatus.

In the course of a paper reviewing the publications and catalogue service of H.M. Stationery Office, Mr. P. McGrath, director of publications, said that the Stationery Office had again been reviewing its catalogue practice and had decided to initiate informal discussions with representative librarians with the view of achieving a compromise which might yield a catalogue more suited to modern requirements. Mr. G. A. Carter, borough librarian of Warrington, in a paper reviewing capital expenditure on building, included both public libraries and school libraries and also libraries in industry (but without giving costs) and in universities, where the estimated cost of five new library buildings due for completion next year was £1,925,000, roughly equivalent to the total expenditure on all new public library buildings in the past twelve years, although in all fourteen university libraries the book stock had increased by only 1·5 million compared with 24 million in public libraries. Mr. Carter also cited figures showing the extreme variation in expenditure on libraries by different local authorities, and he, too, insisted that the new National Lending Library for Science and Technology would not dispense with the need for technical libraries in the municipal and county library systems.

In a stimulating paper of some general interest, Dr. J. Trenaman, liaison officer for further education, British Broadcasting Corporation, under the title "Libraries as a Social Force", described a survey of opinion towards broad educational ends, from which he concluded that about 55 per cent of those in the sample were at least receptive to new and even unwelcome ideas, while the remaining 45 per cent were resistant, at least to the extent of avoiding unaccustomed ideas or not being interested. This resistant sector had usually received only an elementary early education, whereas those who were interested in education had had a fairly good early education, about half having been to a secondary school. They were interested in the more serious radio and television programmes and were also members of a library. There was an upper level of 25 per cent of the whole sample who had mostly received a grammar school education, with a keen interest in further learning and who would be the more serious readers in the libraries. Dr. Trenaman believes that the machinery of education as a whole operates selectively, and accordingly the chief responsibility for adult education rests upon the informal agencies, especially the public library service, the Press and the broadcasting authorities because they have an access denied to all other information agencies. He also emphasizes the profound and durable influence of our early education.

EFFECTS OF PLANT DECOMPOSITION PRODUCTS IN THE SOIL

THE inhibitive effects, on the germination of seeds and on seedling growth, of products from decomposing plant materials in soil have been examined by Z. A. Patrick and L. W. Koch (*Canad. J. Bot.*, 36, 621; 1958). Substances capable of inhibiting the respiration, germination and growth of tobacco seedlings were obtained after residues from timothy, corn, rye or tobacco plants had been allowed to decompose under appropriate conditions in the soil. Bio-assay tests, based on manometric methods, made it possible to determine some of the conditions under which the decomposition gave rise to phytotoxic by-products and to obtain rapidly an accurate measure of the degree of their toxicity.

Among the factors affecting the production of the toxic products, the species and stage of maturity of the plant material added, the water content and *p*H of the soil, and the length of the decomposition period, were the most important. Substances capable of reducing the respiration of tobacco seedlings by 50–90 per cent were consistently obtained when any of the plant residues examined had been decomposing for 15–25 days under conditions of high soil moisture and a *p*H value of the soil solution below 5·5. Timothy yielded substances with the highest toxic activity, followed by corn, then rye, and finally, tobacco. Aqueous extracts of unamended soil or of macerated tissues, prepared either before decomposition or when decomposition was inhibited by autoclaving, were not toxic. The toxic substances, obtained by water extraction, showed an inhibiting effect on respiration of tobacco seedlings after an exposure of less than one hour and also induced darkening and necrosis of root cells. Some extracts affected the cells of the apical meristem most severely while others affected only the cells of the elongation region.

The toxic substances have not yet been identified, but they were relatively non-specific in their action, affecting several test plants in approximately the same manner. Many of them possessed antifungal activity. They were soluble in water, insoluble in petroleum ether, stable in acid, and most active in the *p*H range 4·5–5·8. They were precipitated by alkali and their activity was markedly reduced when they were readjusted to the acid-range. They were also stable to heat and did not lose their activity in storage at 1–3° C. provided they were covered by a layer of toluene. Because of their rapid production and their marked injurious effects on various plants, the authors consider that these toxins may be important under field conditions as the primary factor in some root rots and in predisposing plants to attack by organisms not normally regarded as being pathogenic.

THE NATIONAL INSTITUTE OF AGRICULTURAL BOTANY

THE report for 1957 of the National Institute of Agricultural Botany has recently been published*. The Trials Branch of the Institute has, as usual, carried out an extensive programme of work and the performance of a large number of varieties of the main agricultural and horticultural crops has been assessed. A very special requirement of sugar beet varieties is resistance to bolting, and the results are given of a special series of early-sown sugar beet trials designed to test resistance to premature flowering. The new variety from the Cambridge Plant Breeding Institute, known as Cambro, gave less than 1 per cent of bolters compared with commercial varieties where the percentage varied from 5 to 20. The potato trials have included for the first time a number of foreign varieties from the Continent and North America. The work of the Seed Production Branch has continued to expand, and as well as administering the various field approval and seed certification schemes the Branch has intensified its inquiries into problems of seed production.

The report covers the first full season of operation of the national scheme for the comprehensive certification of herbage seeds. In launching a scheme covering 25,000 acres in its first season, the certifying authority needed, and was fortunate to receive, the full and willing co-operation of all participants. Some 824 growers and 93 merchants took part in the production of 53,500 cwt. of British certified seed. With the co-operation of the Seeds Branch of the Ministry of Agriculture, Fisheries and Food, check samples were drawn from most lots of certified seed and have been tested and then grown in plots for verification purposes. The Official Seed Testing Station received a very similar number of samples in the year under review compared with the previous year, but the proportion of cereals to clovers and root and vegetable samples was much greater because of the very different weather conditions experienced in the two years. The number of samples of each variety of cereal received for testing is some indication of the relative popularity in the country as a whole, and this information is summarized in a table. A notable feature is the disappearance from the list of four old-established varieties, Squarehead's Master, Wilma, Holdfast and Minister. Among the barley varieties, the proportion of Proctor has further increased. The report refers to a number of building developments, including extension to the main building, a cold store and a new glass house.

THE COLOMBO PLAN

THE sixth annual report* of the Consultative Committee for the Colombo Plan for co-operative economic development in south and south-east Asia, as usual, is in three parts. The first includes a general review of economic progress in the area and of the task ahead; the second summarizes the position in individual countries; and the third directs attention to some contributions to economic development made under the Plan and summarizes the contribution of technical assistance in particular.

Further progress in economic development in the area is recorded and the growth of *per capita* real income appears to have been maintained in spite of balance of payment difficulties and increased internal inflationary pressures. Agricultural production, as well as industrial and mining output, in general, showed an upward trend, but exports did not keep pace with the expansion of imports; prices of some of the main products of the Colombo Plan countries fluctuated, and as a result of these fluctuations and of higher prices of imports, the terms of trade worsened for many countries in the region.

Several countries in the region have now approved development plans, and all are evolving programmes designed to accelerate development. Experience in 1957, however, has emphasized the risk that the pace of development may outrun the availability of resources, and consequently the implementation of development plans should permit re-phasing to match the resources available. Once again, the report stresses the desirability for the countries of the area to pursue policies which serve to attract capital, domestic and external, into development projects and to assure the effective utilization of such capital. A pointed reference is made to the need for consideration of such factors as apprehensions as to the security of investment, difficulties with administrative and financial procedures and restrictions, and uncertainties about the incidence and weight of taxation, all of which could offset the attractions of the region.

Again, the problems of the different countries vary considerably, and accordingly the methods of meeting their needs vary widely also. This is brought out particularly in technical assistance, where some countries need help mainly in the shape of highly qualified missions specially equipped to deal with the planning or implementation of major projects, while others seek quite simple skills. It is important that technical assistance should fit the individual needs of each country, and continuing care is required to ensure that technical resources are not wasted. Continual reference is made in the report to the search by the countries of the area for additional resources, more capital, more equipment, and more managerial and technical skill. Although there are signs of strain in some of the more highly developed as well as in the less-industrialized countries, the situation is not regarded as discouraging, because there are signs that the urgent tasks of development and the raising of living standards are being tackled with speed and energy.

Since 1950, training has been extended to about 13,000 trainees from countries of the area, while about 6,000 experts have been provided by Colombo Plan members and United Nations agencies. Australia alone has contributed £3,440,019 to technical assistance, and during 1956–57 spent £5 million on capital and technical assistance, including £200,000 on technical equipment. Another 439 trainees were received and sixty new appointments of technical experts were made, bringing the total in the field in June to sixty-six. Canada's contribution to capital projects and technical assistance amounts to 196·7 million dollars, of which 34·4 million will be for 1957–58, and more than 4 million dollars (1·4 million dollars in 1956–57) on technical assistance. Since 1951, 712 fellows and scholars have been trained in Canada, and 201 of these were still there in June 1957, while 100 experts have been sent abroad, of whom 35 are at present carrying out assignments in seven centres. New Zealand's contribution for capital and technical assistance will amount to £7 million by June 1958, expenditure on technical assistance totalling £744,000 by June 30, 1957, under which training had been provided for 459 persons (148 in 1956–57) and 72 New Zealand experts provided (16 in 1956–57).

The United Kingdom has since 1951 made available to countries in the area, by way of grants, loans, credits and technical assistance, £92 million, including £2·7 million for technical co-operation up to June 30, 1957, with forward commitments of £1,275,000. Of this, £862,540 has been for research and training equipment, with further commitments of another £786,895. By June 1957, 1,582 trainees had been taken, including 333 from non-Commonwealth countries, and in collaboration with the United Kingdom steel industry and the Government of India up to 300 Indian steel workers are to be trained in the United Kingdom for managerial and technical posts at the new steel works at Durgapur. Of 263 experts provided by the United Kingdom, 23 have gone to non-Commonwealth countries. United States Government economic and technical assistance to Colombo Plan countries during the year totalled 900 million dollars, bringing the total since 1950 to more than 3,000 million dollars. During the year, more than 1,000 technicians and students were taken to the United States under the Mutual Security Programme and 500 sent to third countries such as Japan and the Philippines, while about 550 were taken to the United States under the United States International Educational Exchange Programme. Representatives of sixteen nations of the Colombo Plan Consultative Committee met as a working group in Washington to discuss the United States offer of assistance for establishing a regional nuclear centre to serve the needs of the participating countries.

---

* Colombo Plan for Co-operative Economic Development in South and South-East Asia. Sixth Annual Report of the Consultative Committee, Saigon, Viet Nam, October 1957. Pp. 166. (Cmnd. 315.) (London: H.M. Stationery Office, 1958.) 6s. net.

Summarizing the contribution made by technical assistance, the report recognizes that the world scarcity of technical man-power must limit the supply available for the Colombo Plan. By June 30, 1957, expenditure on technical assistance was more than £8 million, including £1·8 million on equipment, and 1,858 persons were receiving training, although the number of new training places declined from 1,552 to 1,395. At the end of the year about 1,400 experts were assigned to countries of the area. Stress is laid on the scope for help from outside the area in developing adequate training institutions, although success depends primarily on the initiative of the institutions themselves, and also on the encouraging increase in the number of countries in the region now providing training places to other countries in the region (Ceylon, India, Indonesia, Malaya, Pakistan, Thailand and Singapore) as against three countries in the previous year. The technique of team work is being used to an increasing extent and within the United States programme some thirty contracts have been arranged with universities of countries within the area to help them develop curricula, teaching methods and research facilities as well as adequate laboratories and libraries.

INTERACTION OF FORMALDEHYDE AND TETRAHYDROFOLIC ACID AND ITS RELATION TO THE ENZYMIC SYNTHESIS OF SERINE

By Dr. R. L. BLAKLEY

Department of Biochemistry, John Curtin School of Medical Research, Australian National University, Canberra

THE reaction between glycine and formaldehyde to form serine in the presence of an enzyme from liver[1] requires, as a co-factor, tetrahydrofolic acid (FH_4, I), which is believed to act by forming a reactive complex with formaldehyde. The structure of the 'active formaldehyde' was first postulated as N^5,N^{10}-methyleneFH_4 (III) in 1954[1], although N^5-hydroxymethylFH_4 (II) is also a possible structure[2]. Formaldehyde is bound strongly by 1 : 2-diamines with the formation of bridged structures. Thus it was demonstrated that N,N′-diphenylethylenediamine reacts readily with formaldehyde to give a stable cyclic product[3]. It might be expected, therefore, that FH_4, which is also a 1 : 2-diamine, would react with formaldehyde to give III, and that this compound would be stabilized to oxygen by the presence of the firmly bound methylene bridge. Although the product of formaldehyde reaction with FH_4 was found to be somewhat more stable than FH_4 itself, it was nevertheless very sensitive to oxygen, for in aqueous solution it rapidly lost coenzyme activity when shaken under air[3]. This sensitivity to oxygen has been confirmed by spectrophotometric studies. When a solution of FH_4 is diluted with phosphate buffer (*p*H 7·2) to a concentration of 5×10^{-5} *M* the spectrum changes within a few minutes from that of FH_4 ($\lambda_{max.}$ 298 mμ) to that of oxidized products with $\lambda_{max.}$ at shorter wave-lengths (finally 275 mμ). If the diluent contains formaldehyde the rate of change due to oxidation is less, but even in the presence of 10^{-3} *M* formaldehyde it is about 3 per cent of that occurring in absence of formaldehyde. In this laboratory, paper chromatography of reaction mixtures has yielded no clear separation of a product with R_F different from that of FH_4 as reported by others[4].

These results were at first interpreted as indicating that II must be the structure of the product, and that it must readily dissociate[3,5]. Investigation of the binding of formaldehyde labelled with carbon-14 by FH_4 and related hydropteridines indicated that approximately one molecular proportion of formaldehyde was bound by FH_4, smaller amounts by N^{10}-formylFH_4 and 2-amino-4-hydroxy-6-methyltetrahydropteridine and a negligible amount by leucovorin[5]. These results have been confirmed and extended by determination of the formaldehyde concentration in equilibrium with known concentrations of hydropteridines. Since tetrahydropteridine is rather unstable, tetrahydroquinoxaline, a close

Table 1. Approximate Dissociation Constants for the Products formed by the Reaction of Formaldehyde with Hydropteridines and Tetrahydroquinoxaline

	Base	Dissociation constant of product = $\frac{[HCHO]\,[base]}{[product]}$
Group *A*	FH_4	0·0004
Group *B*	FH_2	0·01
	N^{10}-formylFH_4	0·01
	N^{10}-methylFH_4	0·03
	2-Amino-4-hydroxy-6-methyltetrahydropteridine	0·04
	4-Hydroxy-6-methyltetrahydropteridine	0·04
	Tetrahydroquinoxaline	0·01
Group *C*	N^5-formylFH_4 (leucovorin)	0·41
	N^5-formyl-4-hydroxy-6-methyltetrahydropteridine	0·45

structural analogue, has also been studied. The results are given in Table 1.

The last two compounds of group *B* are substances which contain only heterocyclic nitrogen, and may be presumed to form hydroxymethyl groups by reaction with formaldehyde. The similarity of the dissociation constants for the products formed by all members of this group suggests that hydroxymethyl groups are formed in all cases, and this is in accord with the fact that methylene bridge formation is precluded in N^{10}-formylFH_4 and N^{10}-methylFH_4.

The very high dissociation constants of complexes formed by group *C* compounds in which a formyl group is substituted on the N^5 position may be interpreted to indicate that N^5 is the essential site for formaldehyde combination with hydropteridines (as previously postulated[5]) and that no other single grouping in leucovorin (for example, N^3, N^8, N^{10} or 2-amino) can provide a strong binding site for formaldehyde. This is in contradistinction to recent hypotheses of multiple binding sites in FH_4 for formaldehyde[4]. It also indicates that N,N′-diphenylethylenediamine cannot be considered a true model for FH_4 in its reaction with formaldehyde. However, the unparallelled combination of formaldehyde with FH_4, in which both N^5 and N^{10} are unsubstituted, suggests that in this molecule both these sites are concerned with formaldehyde binding; since only one molecular proportion of formaldehyde is bound, it seems probable that methylene bridge formation occurs.

Another possible explanation of the relatively high dissociation constants of the complexes formed by formaldehyde with group *B* bases concerns the protonation of the N^5-amine group. In these compounds the N^5-amine group might have a *pK* high enough to result in significant protonation at *p*H 7 and it might be this protonation of N^5 which prevents the reaction with formaldehyde from proceeding to completion. In FH_4, on the other hand, the N^5-amine group may be assumed to have a *pK* well below 7, and thus to be unprotonated at this *p*H. This possibility was tested by determination of the *pK* values of the N^5-amine and 4-hydroxy groups of 4-hydroxy-6-methyltetrahydropteridine. Two groups with *pK* values of 10·2 and 4·1 were detected. The similarity of these to the *pK* values of 9·86 for the hydroxy group and 3·57 for the 5-amino group in the related 4,5-diamino-6-hydroxypyrimidine[6] indicates that in 4-hydroxy-6-methyltetrahydropteridine the *pK* of the N^5-amine group is 4·1. Spectrophotometric studies indicated that no groups in 4-hydroxy-6-methyltetrahydropteridine had a *pK* between 4 and 10. Moreover, no increase in formaldehyde binding occurred at *p*H values above 7. Since differences in the *pK* of the N^5-amine group cannot, therefore, account for the difference between the dissociation constants of group *B* complexes and that of the FH_4-complex, methylene bridge formation in the latter is clearly indicated.

Studies of the rate of reaction of 4-hydroxy-6-methyltetrahydropteridine (4×10^{-3} *M*) with formaldehyde (4×10^{-4} *M*) indicated that equilibrium was reached in a few minutes. Binding of formaldehyde by FH_4 (both at an initial concentration of 4×10^{-4} *M*) was also rapid—80 per cent of the formaldehyde reacting in the first minute. This rate of combination far exceeds those which have been attained for enzymic synthesis of serine, so that enzymic catalysis of the combination appears unnecessary and in fact did not occur with partially purified preparations of serine transhydroxymethylase.

Table 2. ABSORPTION SPECTRA OF FH_4 (5×10^{-5} *M*) IN PRESENCE OF 2,3-DIMERCAPTOPROPANOL (10^{-3} *M*) PHOSPHATE BUFFER *p*H 7·0 (10^{-1} *M*) AND VARIOUS CONCENTRATIONS OF FORMALDEHYDE

Formaldehyde concentration *M*	$\lambda_{max.}$ (mμ)	$\varepsilon_{max.}$ (mol.)
0·0	298	28,400
$6 \cdot 67 \times 10^{-5}$	297	29,000
$1 \cdot 5 \times 10^{-4}$	296	30,800
10^{-3}	294	32,000

The combination of formaldehyde with the bases in Table 1 has also been studied spectrophotometrically. FH_4 and the last three compounds of group *B* show definite changes in spectrum in the presence of formaldehyde. Group *C* compounds, FH_2 and N^{10}-formyl-FH_4, show little or no change in spectrum when formaldehyde is added. Group *C* and the last two compounds of group *B* are relatively stable to oxygen and when kept in aqueous solution under air their spectra changed little (group *B*) or not at all (group *C*) over a period of several hours. Other hydropteridines can be protected from oxidative degradation by sulphydryl compounds, the most efficient of which is 2,3-dimercaptopropanol. This is considerably superior to mercaptoethanol and to mercaptoacetic acid; at a concentration of 5×10^{-3} *M* it stabilizes FH_4 (5×10^{-5} *M*) for many hours, and a concentration of 5×10^{-4} *M* is sufficient to stabilize FH_4 for spectrophotometric measurements.

Representative data for spectra shown by FH_4 in the presence of 2,3-dimercaptopropanol at *p*H 7 are shown in Table 2. The higher the initial formaldehyde concentration the greater was the value of the molecular extinction observed, until a maximum value of 32,000 was obtained in the presence of 10^{-2} *M* formaldehyde. There was also a slight shift in the wave-length of the absorption maximum, from 298 mμ in absence of formaldehyde to 294 mμ in the presence of 10^{-2} *M* formaldehyde. No evidence was obtained for the formation of complexes with absorption maxima at 290–293 mμ, as recently claimed[4].

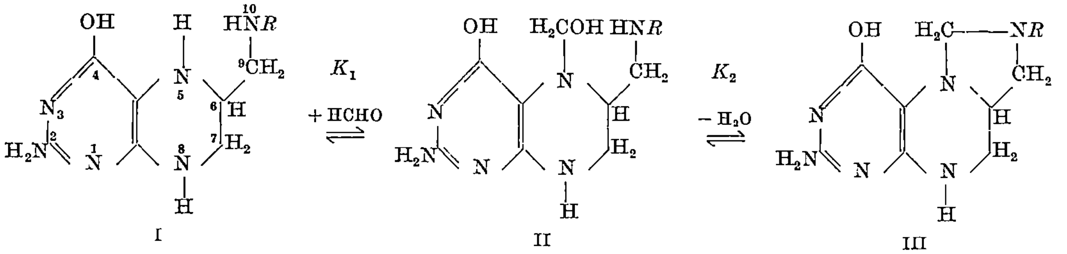
The variation in the wave-length of the absorption maximum and in the extinction coefficient with formaldehyde concentration is believed to be due to the reversibility of the reaction of FH_4 with formaldehyde, rather than to the formation of a series of different complexes[4]. Evidence for this conclusion was obtained by studying the effect of bisulphite on the spectrum of FH_4. The spectrum of FH_4 (5×10^{-5} *M*) in the presence of phosphate buffer *p*H 7 (10^{-1} *M*) and 2,3-dimercaptopropanol (10^{-3} *M*) did not change at an appreciable rate on addition of sodium bisulphite (final concentration $3 \cdot 3 \times 10^{-4}$ *M*). If formaldehyde ($1 \cdot 5 \times 10^{-4}$ *M*) was first added to the solution of FH_4 and the reaction allowed to proceed to equilibrium as shown by the spectrum change, addition of sodium bisulphite then produced a rapid reversal of the spectrum change. This may be interpreted as being due to the dissociation of methylene-FH_4 as a result of the reaction of formaldehyde with bisulphite. Nine extinction values for FH_4 solutions (5×10^{-5} *M*) equilibrated with various concentrations of formaldehyde have been used to calculate the dissociation constant of the complex. A value of $4 \cdot 79 \pm 0 \cdot 30 \times 10^{-5}$ *M* was obtained at *p*H 7·2.

As expected, the time for attainment of equilibrium was inversely proportional to the initial concentration of formaldehyde; in agreement with the results of rate experiments reported above, spectrophotometric measurements showed that equilibrium was established between FH_4 (5×10^{-5} M) and formaldehyde ($6{\cdot}67 \times 10^{-5}$ M) in about 10 min. Reaction in presence of 10^{-2} M formaldehyde was too rapid to measure.

Determination of the dissociation constant for the complex formed by FH_4 and formaldehyde in presence of 5×10^{-4} M 2,3-dimercaptopropanol gave the value $5{\cdot}12 \pm 0{\cdot}16$. The agreement between this value and that obtained in presence of 10^{-3} M 2,3-dimercaptopropanol indicates that at these levels 2,3-dimercaptopropanol does not bind significant amounts of formaldehyde. In the presence of concentrations of 2,3-dimercaptopropanol greater than 10^{-3} M, however, the values obtained for the dissociation constant were high and inconsistent. This is believed to be due to the fact that 2,3-dimercaptopropanol, like other sulphydryl compounds, reacts with formaldehyde and forms a complex with a high dissociation constant, so that significant amounts of formaldehyde are bound only at relatively high concentrations of 2,3-dimercaptopropanol. Evidence that FH_4 and formaldehyde react to form the same final product in the presence of 2,3-dimercaptopropanol as in its absence was found in the fact that 10^{-3} M 2,3-dimercaptopropanol did not alter the spectrum change occurring when 10^{-2} M formaldehyde was added to a solution of FH_4 at pH 7.

The failure of others to detect a non-enzymic reaction between dilute solutions of FH_4 and formaldehyde[4] may be due to the use of high concentrations of 2-mercaptoethanol (10^{-2} M), and this may also account for some other discrepancies. In any event, it has been found in this work that 2-mercaptoethanol (Eastman Kodak, at least 92 per cent in sulphydryl form) was ineffective compared with 2,3-dimercaptopropanol in protecting FH_4 from oxidation.

The following scheme is consistent with the results reported above :



where R is 
where the overall equilibrium constant, K, is 2×10^4 M^{-1}. Since N^{10} binds formaldehyde very weakly compared with N^5 (Table 1), II probably occurs as an intermediate in the formation and dissociation of III. By analogy with compounds of group B in Table 1, the dissociation constant of II may be expected to be about $0{\cdot}03$ M, so that K_1 = approx. 30 M^{-1} and $K_2 = K/K_1 = 667$. Hence at equilibrium methyleneFH_4 exceeds hydroxymethylFH_4 by a factor of about 700.

Addition of glycine and serine transhydroxymethylase to a solution of methyleneFH_4 resulting from equilibration of FH_4 (5×10^{-5} M) with formaldehyde ($1{\cdot}5 \times 10^{-4}$ M) in presence of 2,3-dimercaptopropanol (10^{-3} M) at pH 7·2 caused a change of the spectrum from that of methyleneFH_4 to that of a mixture of methyleneFH_4 and FH_4. At high glycine concentrations approximately 50 per cent of the methyleneFH_4 was converted to FH_4, resulting in the same spectrum as that obtained by adding sufficient formaldehyde to FH_4 to produce 50 per cent conversion to methyleneFH_4. As synthetic FH_4 and hence methyleneFH_4 are racemates due to the asymmetric centre introduced at C^6 during hydrogenation of folic acid, it appears likely that transhydroxymethylase catalyses a reaction with only one of the optical isomers. Neither enzyme nor glycine alone changed the spectrum of methyleneFH_4.

When L-serine was added to FH_4 (5×10^{-5} M) stabilized by 2,3-dimercaptopropanol (10^{-3} M) at pH 7·2 (phosphate buffer, 0·1 M) no change occurred. Subsequent addition of serine transhydroxymethylase caused a spectrum change corresponding to approximately 50 per cent conversion of FH_4 to methyleneFH_4. Even at high concentrations of L-serine the reaction did not proceed further than 50 per cent, presumably because the enzyme again catalysed reaction with only one isomer of the synthetic FH_4. Neither enzyme alone, nor enzyme together with D-serine, caused the spectrum change. The spectrum obtained when FH_4 was equilibrated with excess L-serine and enzyme was the same as that produced when sufficient formaldehyde was added to FH_4 to convert 50 per cent to methyleneFH_4. When excess formaldehyde was added to FH_4 which had been first equilibrated with L-serine and enzyme, the final spectrum had the same $\lambda_{max.}$ and extinction coefficient as that resulting from addition of excess formaldehyde to FH_4 alone.

Isolation of ethanol-insoluble barium salts from larger-scale incubations of DL-serine, enzyme and FH_4 gave a product with a spectrum in 0·1 N sodium hydroxide similar to that of methyleneFH_4. When the molecular extinction of the product was determined, however, it was found to be only about half that of methyleneFH_4 ; this is believed to be due to the rapid decomposition during isolation of the unreacted isomer of FH_4 giving rise to contaminating products with little absorption at 298 mμ. The material was active as coenzyme for enzymic synthesis of serine but decomposed in solution to an inactive product. The decomposition was accelerated by shaking in air or oxygen, by increase in temperature and by dilution. Under hydrogen, decomposition was negligible and catalytic hydrogenation restored some coenzyme activity to the decomposition products. The decomposition, like the decomposition of synthetic methyleneFH_4, was dependent on pH, being fastest at about pH 5 and negligible at pH 13. This increased stability at higher pH seems to be due to the ionization of the 4-hydroxy group, since the effect becomes marked in the pH-range in which this group dissociates.

These results indicate that the only difference between synthetic methyleneFH_4 and the product of the enzymic reaction of L-serine and FH_4 is that synthetic methyleneFH_4 is a racemate, whereas the enzymic product is a single stereoisomer. No evidence was found that the non-enzymic reaction of formaldehyde and synthetic FH_4 produced any material of a different chemical nature from that of the enzymic intermediate. Spectrophotometric studies indicated that in the reaction:

$$\text{Glycine} + \text{methylene}FH_4 \rightleftharpoons \text{serine} + FH_4$$

the equilibrium lies to the left, the constant being about 0·3. Although it has been assumed that it is methyleneFH_4 which reacts enzymically, the data are also consistent with N^5-hydroxymethylFH_4 (in rapid equilibrium with methyleneFH_4), being the actual participant in the reaction. The coenzyme activity of FH_2 may be due to the contamination of FH_2 preparations by FH_4. If, however, FH_2 is indeed a coenzyme and if it reacts with formaldehyde to form only N^5-hydroxymethylFH_2 as the value of the dissociation constant seems to imply, then N^5-hydroxymethylFH_2 is capable of reaction with glycine in presence of serine transhydroxymethylase, without mediation of a methylene-bridged compound. By analogy this would suggest that N^5-hydroxymethylFH_4 rather than methyleneFH_4 is the substrate for serine transhydroxymethylase; furthermore, a simple reaction mechanism is possible if this is the case. Enzymic dehydrogenation of the formaldehyde-FH_4 complex to N^{10}-formylFH_4 via N^5,N^{10}-metheneFH_4 (anhydroleucovorin) is more easily conceived as involving methyleneFH_4 as substrate[7].

In the above discussion no mention has been made of the fact that glycine and serine react in the form of Schiff's bases of pyridoxal phosphate. In the spectrophotometric experiments reported here no pyridoxal phosphate was added, but previous evidence indicates that it is firmly bound to serine transhydroxymethylase. It may be assumed that, prior to their interconversion, serine and glycine react with bound pyridoxal phosphate to form Schiff's bases.

I should like to express my indebtedness to Dr. D. J. Brown for generous gifts of pteridines, to Mr. J. McKeough for skilled technical assistance, and to Prof. A. H. Ennor and other members of this Department for helpful advice and criticism.

SOME NEW VERTEBRATE FOSSILS FROM THE PANCHET SERIES OF WEST BENGAL

By Dr. PAMELA LAMPLUGH ROBINSON
Department of Zoology, University College, London

THE Panchet series of rocks form part of the Gondwana System of India, and their age has been a subject of controversy ever since they were first named by W. T. Blanford[1] in 1861. Suggestions have ranged from Upper Permian to Upper Triassic, inclusive. The purpose of this communication is to make a preliminary announcement of some new discoveries of vertebrate fossils from the Panchets which do much to solve the question of the age of these rocks.

The Panchet series occur chiefly in the Raniganj coalfield of West Bengal, where they form a cover to part of the coal-bearing Damudas. The succession of Gondwana rocks in the Raniganj coalfield is:

- Supra-Panchets
- Panchet series
- Damudas
  - Raniganj measures
  - Ironstone shales
  - Barakar measures
- Talchir series

All these rocks were formed under continental conditions during late Palæozoic and Mesozoic times. They accumulated in a depression or valley in a landscale carved out of Archæan rocks, and are themselves largely erosion debris which was derived from neighbouring hilly areas made up of Archæans. The upper part of the Panchet series consists mainly of sandstones with subordinate shales, while the lower part is mainly shales with subordinate sandstone bands. No trace of coal has ever been found in the Panchet series.

In 1860 Dr. Blanford and Mr. Tween discovered some fossils in the Panchet series. Plant remains were found in the lowest beds and were described by Feistmantel[2] in 1880. Of the eleven species described, seven are also found in the underlying Damuda formations. Isolated and fragmentary bones, often rolled and water-worn, were discovered in conglomeratic sandstones in the upper part of the Panchets, where these rocks crop out in the bed of the River Damuda. These bones, usually teeth, fragments of jaws, vertebræ and limb bones, were described by Huxley[3], and later collections of similar material were described by Lydekker[4]. These authors identified a fauna consisting chiefly of labyrinthodonts and dicynodonts. A few years ago, Dr. M. R. Sahni, palæontologist to the Geological Survey of India, asked a field officer, Mr. S. N. Puri, to make a further collection from the conglomeratic Upper Panchet sandstones. Mr. Puri found fossiliferous outcrops at a number of places in the southern part of the coalfield, made an excellent map of these localities, and brought back a collection which included one good roof of a labyrinthodont skull, as well as a large number of isolated bones and fragments. The labyrinthodont is being described by Prof. F. von Huene and Dr. Sahni.

Permo–Triassic labyrinthodonts are only rarely of use in correlation and dating. Some dicynodonts are very useful horizon-markers, but since this group has a considerable uniformity of general structure, while varying a great deal in detailed morphology, it is necessary to have good specimens before a proper assessment of affinity can be made. Dicynodonts are locally common in the Permian *Tapinocephalus* zone of South Africa, in the next, *Endothiodon*, zone they are fairly abundant, and they are exceedingly common and varied in the succeeding *Cistecephalus* zone. In the *Lystrosaurus* zone, though individuals are often abundant, almost all belong to the genus which gives its name to the zone. The genus is not found outside this zone and is therefore an excellent zone fossil. During the rest of the Trias, dicynodonts are restricted to a few genera of large size. Thus, the presence of dicynodonts in the Panchet series does not provide a means of dating these rocks without the more detailed knowledge of these fossils which only good specimens can provide.

In the re-survey of the Raniganj coalfield made in 1925–28[5], some fish scales were found at a single locality in the lower Panchet shales. Among these, Dr. E. I. White identified a scale of *Amblypterus*, and this lends a distinctly Palæozoic aspect to the lower part of the Panchets, as does the character of the flora.

In the autumn of 1957 I went to India as the guest of the Indian Statistical Institute, at the invitation of the director, Prof. P. C. Mahalanobis. At the beginning of December I visited the Raniganj coalfield as part of a programme of field-work which had as its main object the attempt to discover further vertebrate fossils in various formations of the Gondwana System. The rather fragmentary remains found in some of the Gondwana formations, mainly during the past century and usually by amateurs, suggested that the Gondwana System might be potentially as rich in fossil vertebrates as the famous Karroo of South Africa, and apart from the evolutionary interest of any discoveries which could be made, these would also provide a means of correlating and dating the Gondwana formations. Hitherto, correlations have mainly been made on floral evidence, which is not a very satisfactory tool, but which has had to be used in default of anything else.

The field-work on the Panchets of the Raniganj coalfield was carried out as a collaboration between the Indian Statistical Institute and the Geological Survey of India. Three junior Survey officers, Mr. C. Tripathi, Mr. P. P. Satsangi and Mr. S. T. Rajurka, and two palæontological research workers at the Indian Statistical Institute, Dr. S. L. Jain and Mr. T. K. R. Chowdhury, accompanied me into the field. We found that, in the upper part of the Panchet series, conglomeratic sandstone was very fossiliferous in places, but though part of an amphibian skull roof and a few good specimens of individual bones and jaws were obtained, many of the fossils were fragmentary and no associated skeletons were ever found. The reason for this is plain from an examination of the sandstones. They are all highly false-bedded rocks, and in places even contorted. They evidently represent a large delta tip-heap, into which sand, pebbles and animal bones were swept by a river and its tributaries. The sediment sometimes piled up so fast that it became unstable and slumped a little way down the growing delta front. The shales of the lower part of the Panchet series seemed to form lenses of various sizes, the formation of which could be envisaged as due to the gradual silting up of pools and lakes. Under such conditions, land animals dying in or near to the pools would be more likely to suffer burial without dismemberment. We therefore began to search the shales in the lower part of the Panchets, and Mr. P. P. Satsangi was the first to discover in them the skeleton and skull of a dicynodont. The skull could immediately be identified as that of a species of *Lystrosaurus*. Five skulls and some more skeletal remains of *Lystrosaurus* were found, but no other tetrapods so far.

The discovery of a number of good specimens of *Lystrosaurus* in the Panchets allows the immediate correlation of the series with a zone of the Karroo succession in South Africa. The zones of the South African succession, and their dicynodont faunas, are :

Beaufort series :		
Cynognathus zone	*Kannemeyeria*	Lower Triassic
Procolophon zone		
Lystrosaurus zone	*Lystrosaurus* and *Myosaurus*	
Cistecephalus zone	*Dicynodon*, *Cistecephalus*, and other genera with 195 spp.	Upper Permian
Endothiodon zone	*Dicynodon*, *Endothiodon*, and other genera with 27 spp.	
Tapinocephalus zone	*Dicynodon* and other genera with 8 spp.	

Since *Lystrosaurus* has also been discovered in Sinkiang[6], the new discovery in the Indian Panchets is of interest as going some way towards providing a geographical link between Sinkiang and South Africa in the distribution of the genus in early Triassic times.

Only one other associated skeleton of a fossil tetrapod has ever been found in the entire Gondwana System. The previous discovery was made almost a hundred years ago by an Army officer, Major Gowan, who found the skeleton and skull of the labyrinthodont *Gondwanasaurus bijoriensis* at the crossing of a stream by a bullock-cart track some miles south-west of Pachmari. The new discoveries raised hopes about the possibilities in other formations of the Gondwana System, and these hopes have already been realized in field-work done in other areas by me, in collaboration with Dr. Jain and Mr. Chowdhury. The fossils discovered are still under investigation, but comprise skeletons and skulls instead of the fragments previously known. The Gondwana formations can evidently be regarded as a very hopeful source of fossil vertebrate material, and certain formations provide the only possibility of obtaining a continental fauna of Lower to Middle Jurassic age anywhere in the world.

A rather more detailed account of the work done on the Panchets of West Bengal, with a preliminary discussion of the new fossil material, will appear elsewhere, and a detailed description of the new *Lystrosaurus* specimens will be undertaken by Tripathi and Satsangi at the Geological Survey of India.

It is a pleasure to thank Prof. Mahalanobis for the invitation and facilities which made my work in India possible. I am grateful to many members of the Indian Statistical Institute for their help. I should also like to thank Mr. V. P. Sondhi, director of the Geological Survey of India, for much help and friendly co-operation, and Mr. K. K. Datta for facilities in the field.

Stabilization of Water Mists

The stability of a water mist formed in an atmosphere that is not fully saturated is severely affected by droplet evaporation. Thus a water-drop 10μ in radius suspended in air at 20° C. and 80 per cent relative humidity can be shown to have a life of only 2·4 sec. Richardson[1] describes experiments in which no water-drop of radius less than 200μ, dropped from the top of a 40-m. tower, reached the bottom.

The possibility of reducing the coefficient of evaporation of a plane water surface from 4×10^{-2} to 6×10^{-6} by coating it with a monomolecular layer of a long-chain fatty acid has been demonstrated[2], and reductions in the rate of evaporation of the order of 50 per cent have been obtained by means of monolayers of cetyl-stearyl alcohol[3]. Bradley[4] pointed out that, with droplets of Stokesian or smaller size, a corresponding reduction in the evaporation coefficient could be expected to result in a very much greater reduction of the rate of evaporation than with a plane surface. This was shown to follow from a simplified form of Fuchs's[5] equation of droplet evaporation :

$$\frac{dm}{dt} = \frac{-4\pi a w c_0}{1 + (D/a\nu\alpha)}$$

in which dm/dt is the rate of evaporation of the droplet, a its radius, w the mass of a vapour molecule, α the evaporation coefficient, c_0 the saturation concentration of vapour in air, D its diffusion coefficient, and $\nu = \sqrt{(kT/2\pi w)}$, where T is the absolute temperature.

The present communication describes an attempt at producing a water mist each drop of which is coated with a monolayer. This was done by dispersing in the water a mixture of almost equal parts of cetyl and stearyl alcohol in a concentration of 0·2 per cent by weight, using as a dispersing agent 0·1–0·2 per cent of a compound of "fully hardened sperm alcohol and 15 molecules (average) of ethylene oxide". The dispersion is stable and can be atomized. At the low mean droplet radii of the aerosol so generated (mean surface radius 7·5μ) this overall concentration proved sufficient to coat the droplets. This is because the rate of diffusion of water into the air at the droplet surface is about 10^4 times that of the dispersed alcohol into the droplet interior ; once evaporation starts, monolayers of high surface pressure may be expected to form on the surfaces.

To test the efficacy of the monolayers the dispersion was atomized by means of a compressed-air nozzle and introduced into the top of a vertical tube, 1 ft. in diameter and 15 ft. high, the aerosol being sampled during its descent at various levels inside the tube. The vertical tube was kept at a temperature of 28·3° C. and the humidity varied over a wide range. Counts made of the various samples gave droplet size distributions which enabled the rate of evaporation to be calculated as a function of relative humidity. The experiments were repeated with water alone. Fig. 1 shows the variation with relative humidity of the initial radius of droplets, both water and dispersion, that just fall through 12 ft. in these conditions before completely evaporating.

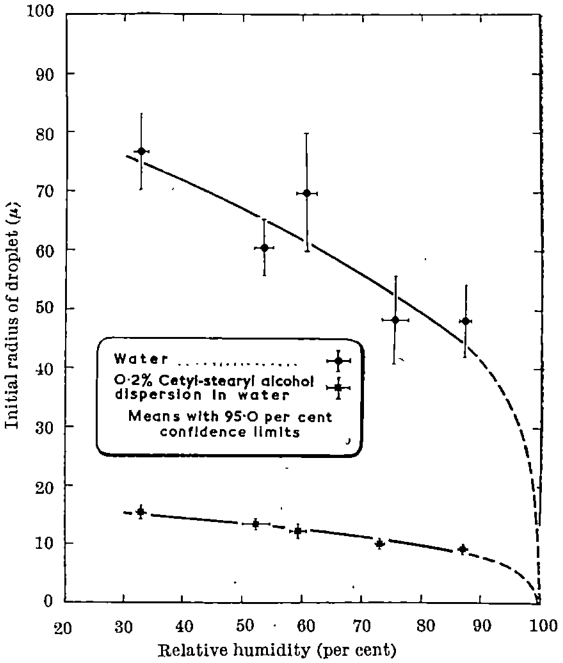

Fig. 1. Effect of humidity on the initial radius of a droplet that falls 357 cm. before completely evaporating. (Crown copyright, S.M.R.E.)

Measurement of the evaporation coefficient of the dispersion gave a minimum value of $1{\cdot}5 \times 10^{-5}$ at high concentrations. Substituting this value in Fuchs's equation, it was found that the latter predicted the rate of evaporation of the dispersion droplets and its variation with relative humidity, within the size-range used, with some accuracy. The equation could thus be used to calculate the total life of the droplets shown in Table 1.

Table 1. Life of Droplet at 20° C. and 80 per cent Relative Humidity

Radius of droplet (microns)	Water (sec.)	Dispersion (sec.)
5	0·64	656
10	2·35	1,314

A considerable increase in the life of a droplet and, hence, stability of mist is thus obtained. In more recent experiments it was found that concentrations of 0·1 per cent of alcohols and of dispersing agent gave results that did not differ significantly from those with 0·2 per cent of these agents.

A more detailed paper is to be published in due course. We wish to thank Dr. T. G. Jones, Research Department, Unilever, Ltd., for suggesting and preparing the dispersing agent and the Ministry of Power for permission to publish this communication.

Diffraction Anomaly in Polarizing Microscopes

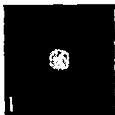
The image quality of the polarizing microscope has never been critically examined, perhaps because the instrument was used primarily for determining optical constants of crystals and fibres, rather than for studying fine details of the object. We have recently re-examined its reliability and find that unless the rotation at the lens surfaces is rectified, the unit diffraction pattern is not an Airy disk but a four-leaf-clover pattern, and that the resolution and contrast may be spurious.

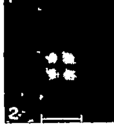
In a conventional polarizing microscope the field between crossed polarizers illuminated by a bright source is never completely dark. If the microscope is equipped with lenses completely free from strain birefringence a polarization cross is observed at the back aperture of the objective lens. The light in this cross is introduced almost exclusively by rotation of the plane of polarization at the oblique interfaces between the polarizer and the analyser[1,2]. The rotation is a consequence of differential transmittance of the vectors polarized parallel and perpendicular to the planes of incidence and may reach 6 deg. or more at the edge of the aperture. This not only lowers the extinction of the polarizing microscope at high numerical apertures, but also modifies the aperture function of the system even when the condenser diaphragm is closed. As a result, the diffraction image of a pin-hole between crossed polarizers is no longer a regular Airy disk (Fig. 1) but a clover-leaf pattern possessing a dark centre and a dark cross (Fig. 2). Its intensity is expressed by :

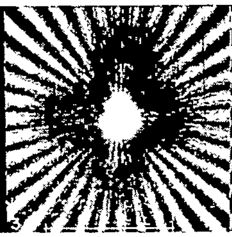
$$I \simeq \sin 2\theta \, J_3(r)/r \qquad (1)$$

where θ and r are polar co-ordinates in the image plane (θ is measured from the plane of polarization of the polarizer and r is measured in diffraction units) and $J_3(r)$ is a Bessel function of the third order.

Densitometry of photographs of sub-resolution pinholes taken through a special strain-free polarizing microscope agrees well with the distribution of intensity calculated from this formula. The special polarizing microscope used for this work was designed jointly by one of us (S. I.) and the American Optical Co. and was constructed at the University of Rochester with generous support from the former. The distribution of intensity along $\theta = \pm \pi/2$ (Fig. 5) shows that the radius of the central maximum in the clover-leaf pattern coincides approximately with the first minimum of the Airy disk. The ratio of the intensity of the central to that of the first diffraction maxima is 10 : 1 in the clover leaf as opposed to 50 : 1 in the Airy disk.







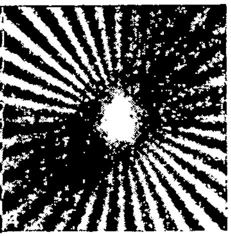


Fig. 1. Airy disk in the absence of a polarizer. The diffraction pattern was obtained by optically reducing a pinhole 20μ in diameter located in front of the lamp to 0·2μ and then re-magnifying. A pair of identical strain-free 97 × oil-immersion objectives with 1·25 numerical aperture was used. The image produced by this system is identical with the image of a 0·2-μ pinhole located at the object space, except that the lens errors are doubled

Fig. 2. As for Fig. 1, but between crossed polarizers. Scale for Figs. 1 and 2, 1·0μ

Fig. 3. Image of a Siemens's test chart between crossed polarizers. Except for the Siemens's star which replaced the pinhole, system identical with that of Fig. 2. Notice reversal of contrast and spurious resolution. Scale for Figs. 3 and 4, 10μ

Fig. 4. Image of same test-chart as in Fig. 3, between crossed polarizers but viewed through the same objectives after they were rectified. The diffraction anomaly has disappeared

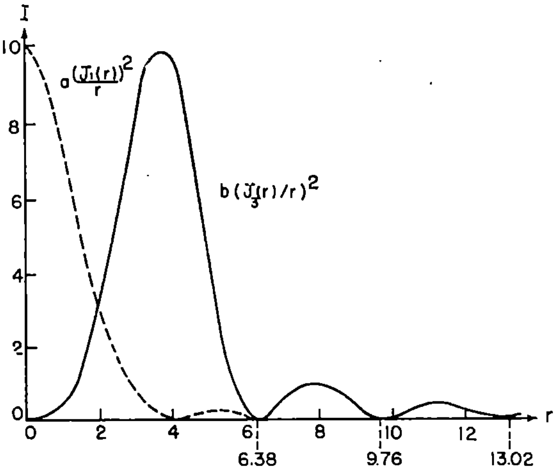

Fig. 5. Intensities (I) of the diffraction image of an unresolved pinhole calculated along the radius (r in diffraction units) at 45° to the plane of polarization. Broken line, Airy diffraction pattern in non-polarized light, or in polarized light with rectified optics. Solid line, with non-rectified optics between crossed polarizers. The curves have been normalized to make the central maxima equal. Microdensitometer tracings of Figs. 1 and 2 agree with the calculated curve to within a few per cent

As the polarizer is rotated away from the crossed orientation the clover leaf changes to a diagonal figure of eight, an ellipse, and finally to the regular Airy disk when the polarizers are parallel. Similar changes are observed when compensators are introduced between crossed polarizers.

When, on the pinhole, a uniaxial crystal is superimposed with its optic axis parallel to the axis of the microscope (Z-cut), the diffraction image of the pinhole between crossed polarizers is again expressed by equation (1) even in the absence of rotation. With parallel polarizers a diffraction image similar to that in an astigmatic system is formed by the extraordinary rays, superimposed on the Airy disk formed by the ordinary rays. These are also the diffraction images of pinholes formed by catadioptric (reflecting) polarizing microscopes without any crystals.

When a crystal is introduced with its axis normal to the microscope axis (X-cut), a highly astigmatic diffraction pattern identical with those reported by Nienhuis for conventional astigmatism is superimposed on the Airy disk. Theoretical formulæ for all these diffraction patterns, except for the X-cut crystal, were calculated by one of us (H. K.) ; they are reported in ref. 3 together with their experimental verifications.

The effect of anomalous diffraction on a periodic absorbing object was determined by observing a black-and-white test chart through a pair of oil-immersion lenses showing a medium degree of rotation. As shown in Fig. 3, contrast reversal and spurious resolution are observed to varying degrees at different orientation of the periodic object.

These diffraction anomalies clearly indicate the danger of using polarizing microscopes or other optical instruments employing polarized light at high angles of incidence[2] without due consideration of the image quality. On the other hand, some of the properties described may be used to advantage for modifying the aperture function and even for obtaining higher 'resolution' in special cases. In general, the Rayleigh criterion of resolving power is not applicable and, instead, it is suggested that the transfer (or response) function of the system be used to evaluate the image.

The diffraction anomalies and the resulting spurious image are practically eliminated with the polarization rectifier[2]. The rectifier corrects the rotation so that the state of polarization is no longer irregular, and a uniformly dark aperture is obtained. Fig. 4 shows the correct image of the same test-chart viewed through a pair of rectified oil-immersion objectives. With rectification, the maximum resolving power of the light microscope can be realized, and the system has been utilized for exact studies of biological objects possessing birefringence down to a fraction of an angstrom unit.

Mosaic Structure of Photographic Emulsion Crystals

CRYSTAL imperfections play an important part in present studies of the formation of the photographic latent image. In large silver bromide crystals it has been shown[1] that silver prints out along individual dislocation lines. Little direct evidence has yet been given on defects within the small grains of photographic emulsions, since neither light microscopy nor electron microscopy has yet proved effective in this field.

It was found by a convergent beam X-ray analysis[2] and by an X-ray microbeam diffraction method[3] that there exist in the grains of some commercial photographic emulsions distinct angular misalignments and sub-structures. In recent studies of X-ray microbeam transmission photographs using a Hilger 'Microfocus Unit' we have now been able to obtain separately resolved structures within the diffraction spots from individual emulsion grains. In some of these spots up to six individual subdivisions can be detected (see Fig. 1*a* and *b*, each of which shows enlargements (×120) of a diffraction spot). Such high-resolution spots were obtained with X-ray tube focal areas of dimensions 4 × 40μ and 100 × 140μ with lead glass capillaries of 10μ diameter as collimators for the incident X-ray beam. As recording material Kodak 'Crystallex' X-ray film was used. Experiments were carried out to show that the grains themselves, and neither the intensity distribution of the focal spot nor the structure of the paper of the envelope of the recording film, is responsible for the effect. This evidence is also supported by the fact that within the same type of photographic emulsion grains different types of characteristic structures of spots can be distinguished within the spotty powder ring. On the other hand, certain other emulsion grains under the same exposure conditions show diffuse diffraction spots (without any sub-divisions) and this effect is probably due to broadening of small crystallites size. (*Note added in proof:* We now have direct evidence that this explanation is correct.)

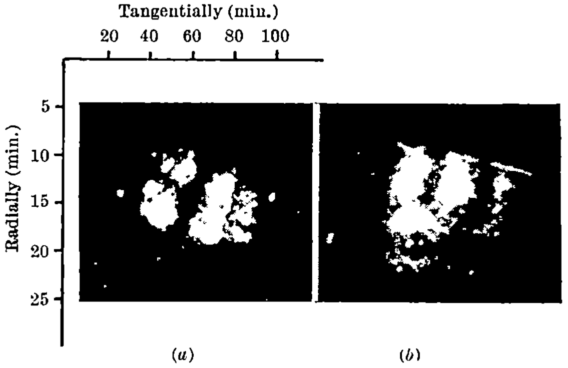

Fig. 1. Enlargements (×120) of diffraction spots taken from a photographic emulsion having grains with a mean diameter of 1μ (*a*) and 1·5μ (*b*). Each group of spots corresponds to a diffraction image of one grain. The scales correspond to the angular displacement of planes in radial and tangential directions

From considerations of the divergence of the X-ray beam, the natural spread of wave-lengths, and the separation of the $K\alpha_1$ and $K\alpha_2$ wave-lengths, it is concluded that the detail within diffraction spots reveals the mosaic structure of the grains. From measurements of the distances between nearest structure elements within diffraction spots it is found that angular misalignments of 3′–4′ between planes are resolved.

Neutron–Proton Interaction

THE present communication suggests a new approach to the proton–neutron interaction and the deuteron problem. We have been able to calculate successfully the binding energy of the deuteron by the suggested interaction. The approach is phenomenological in that the structure of the nucleons has not been taken into account.

It is proposed that the interaction between the nucleons is magnetic. First let us consider a model based on the old quantum theory. Let μ_p and μ_n represent the magnetic moments of the proton (positive) and neutron (negative) respectively, and let r be the distance between them. Then the minimum potential energy in the attractive case is given by:

$$W = \frac{2\mu_p\mu_n}{r^3} \qquad (1)$$

The spin of the deuteron is 1, which suggests a parallel alignment of the neutron and proton spins, and no orbital motion of the two nucleons about their common centre of mass.

The value of r has to be determined by quantum conditions. Turning to the quantization of length, if M_r be the reduced mass of the system, a highly suggestive fundamental length is $h/2\pi M_r c$.

Then the distance in the nth state is given by:

$$r_n = \frac{nh}{2\pi M_r c} \qquad (2)$$

This expression can be justified in other ways also:

(i) In the Bohr atom model, the expression for the radius can be written:

$$r_n = \frac{n\hbar}{M_r c} \cdot \frac{c}{v} \qquad (3)$$

Under the condition $v \rightarrow c$,

$$r_n = \frac{n\hbar}{M_r c}$$

which is the same as (2).

(ii) The Bohr expression for the radius is:

$$r_n = \frac{n^2\hbar}{M_r c} \cdot \frac{1}{\alpha} \qquad (4)$$

where α is the fine structure constant (1/137·04). Current nuclear theories suggest that for the nucleus the corresponding constant is approximately 1. If we assume that $\alpha = 1$ for the nucleus:

$$r_n = \frac{n^2\hbar}{M_r c} \qquad (5)$$

which is the same as (2) except for the power of n.

Substituting the value of r_n in equation (1), we get:

$$W = \frac{2\mu_p\mu_n M_r^3 c^3}{n^3\hbar^3} \qquad (6)$$

In the following, the values of the magnetic moments and masses of neutron and proton have been taken from the paper by Shapiro[1].

For the ground-state:

$$W = -2\left(\frac{2{\cdot}792743e\hbar}{2M_p c}\right)\left(\frac{1{\cdot}913138e\hbar}{2M_p c}\right)\frac{M_r^3 c^3}{\hbar^3} \qquad (7)$$

First we deduce an approximate expression. Putting $M_r \approx M_p/2$, expression (7) becomes:

$$W = -(2{\cdot}792743)(1{\cdot}913138)\left(\frac{M_p c^2}{16}\right)\frac{e^2}{c\hbar} \qquad (8)$$

With $M_p c^2 = 938{\cdot}21$ MeV., this simplifies to:

$$W = -2{\cdot}286 \text{ MeV.} \qquad (9)$$

Next we calculate W by taking the exact value of M_r. As $M_p c^2 = 938{\cdot}21$ MeV. and $M_n c^2 = 939{\cdot}51$ MeV., $M_r c^2 = 469{\cdot}43$ MeV., and equation (6) gives:

$$W = -2{\cdot}291 \text{ MeV.} \qquad (10)$$

This value is in good agreement with the observed binding energy 2·226 (±0·002) MeV. (Wapstra[2]). However, the discrepancy of 0·065 MeV. is well outside the limits of experimental error. Further, it cannot be explained as due to possible errors in the values of the constants involved, as these are known to a high degree of accuracy.

Either of the equations (2) or (5) may be the correct one. By equation (2), $W \propto 1/n^3$, and by equation (5), $W \propto 1/n^6$.

Using the experimental value for the ground-state energy of the deuteron, the first excited state is indicated at 0·278 MeV. or 0·035 MeV. (corresponding to the two possibilities). No excited state of the deuteron has been reported so far. Should it be at 0·035 MeV., it could have been easily missed due to the fact that the transition energy $(W_2 - W_1)$ would be very close to the disintegration energy. Experiments on this point are highly desirable.

Next we consider the wave mechanical treatment. The present suggestion defines a tensor force and we can put:

$$V = -S_{12}J(r) \qquad (11)$$

where $J(r) = -\frac{\mu_p\mu_n}{r^3}$

and $S_{12} = \frac{3(\sigma_1.r)(\sigma_2.r)}{r^2} - \sigma_1.\sigma_2$

where σ_1 and σ_2 are the Pauli spin operators for the proton and neutron respectively.

Usually a mixture of central and tensor potentials is employed[3]. Christian and Noyes[4] have used a pure tensor force in the investigation of p–p scattering.

Equation (11) is also a pure tensor force. But of course one can speak of an 'equivalent central force' (Christian and Hart, ref. 3).

The states $^3S_1$ and $^3D_1$ would be coupled for the present potential, and, following Rarita and Schwinger[3], it is seen that the radial wave functions for the $^3S_1$ and $^3D_1$ states must satisfy the simultaneous equations:

$$\frac{d^2u}{dr^2} + \lambda Eu - 8^{1/2} \cdot \frac{\lambda\beta}{r^3} w = 0 \qquad (12a)$$

$$\frac{d^2w}{dr^2} + \left[\lambda E + \frac{2\lambda\beta}{r^3} - \frac{6}{r^2}\right] w - 8^{1/2} \cdot \frac{\lambda\beta}{r^3} u = 0 \qquad (12b)$$

where $\lambda = 2M_r/\hbar^2$

and $\beta = \mu_p\mu_n$

These equations suffer from the well-known difficulties associated with r^{-3} singularity. Perhaps a 'cut-off' device[5] will have to be used with 'cut-off' at $\hbar/M_r c$.

In view of the fact that in the case of the hydrogen atom results on the basis of old quantum theory and wave mechanics are nearly the same, it may be that for the deuteron also the situation is not very different.

The quadrupole moment of the deuteron is expected to be of the order of r_1^2. With the value of r_1 given by equation (2):

$$Q \sim r_1^2 = 1{\cdot}764 \times 10^{-27} \text{ cm.}^2$$

This may be compared with the experimental value

$$Q = +2{\cdot}73 \times 10^{-27} \text{ cm.}^2$$

There is also the possibility that the interaction may be a combination of a central force and the magnetic tensor force, but the tensor force alone may be responsible for the binding. It may be mentioned that interesting analogies between magnetostatics and the pseudo-scalar meson field have been drawn by Kahana and Coish[6].

Further details of the investigation are to be published later.

An Artificial Aurora

IN a recent communication[1] conclusive evidence has been presented for the artificial production of auroral phenomena by the detonation of a nuclear device in the upper atmosphere. The auroral display in question was observed at Apia Observatory, lat. 13° S., long. 171° W., and is considered to have been produced by a nuclear bomb exploded approximately one hundred miles above Johnston Island, lat. 17° N., long. 169° W.

The distance between Johnston Island and Apia is about 2,200 miles, and hence an explosion 100 miles above Johnston Island could not be seen from the upper atmosphere over Apia. Thus direct radiation from the explosion could scarcely be the cause of the observed aurora. On the other hand, as undoubtedly will have occurred to many people, if a nuclear explosion is produced high enough in the atmosphere, charged particles emitted as a result of this explosion could be guided along the lines of force of the Earth's magnetic field and returned to Earth at a point on the same geomagnetic longitude and opposite geomagnetic latitude. While there will be a small eastwards drift across the lines of force due to the vertical gradient of the Earth's field, it will be only of the order of 100 metres, the exact magnitude depending upon the angle of pitch of the particle's trajectory. Since the geomagnetic equator at a geographic longitude of 170° W. is situated at about 3° N., and the declination in this region is about 10° E., it can be seen that Johnston Island and a region to the north-west of Apia do approximately fulfil these conditions of lying on the same line of force.

In a nuclear explosion, electrons and charged ions will be produced. The electrons will have β-ray decay energies of up to a few million electron-volts and thus, neglecting electrostatic forces, will readily be able to escape from any residual matter above the point of detonation and, on their return to the atmosphere, be able to produce effects at relatively low altitudes. Therefore, it seems that these β-ray electrons can adequately explain the observed phenomena. The charged ions produced at the same time would appear in general not to have sufficient energy to enable them to escape from the region of the explosion.

The duration of the auroral display was between six and seven minutes. The transit time for β-rays between Johnston Island and Apia along a line of force would be only a few hundredths of a second, and for β-rays of lower energy moving in spirals around the lines of force with very small angles of pitch can scarcely exceed a few seconds. However, there appear to be at least two mechanisms operating which explain the long time-scale of the aurora. First, the average life-time of nuclei produced in nuclear explosions which decay by β-emission is of the order of minutes, and, secondly, large numbers of atoms in the upper atmosphere over Apia must have been excited to metastable states which decayed with appreciable life-times.

The demonstration of the possibility of producing aurora artificially at once suggests the great interest that would be attached to studying the effects of any high-altitude nuclear explosions in the auroral belt, or elsewhere at still higher altitudes. Such an experiment would represent the injection of particles into the region of high particle-density recently detected by Earth satellite observations[2], and would enable one to study the storage and propagation of charged particles in this region.

Rate of Accumulation of Nickel in Atlantic Equatorial Deep-Sea Sediments and its Bearing on Possible Extra-Terrestrial Sources

IN a recent communication, Pettersson[1] estimated the rate of accumulation of nickel on the Earth from extra-terrestrial sources on the basis of the nickel-bearing particles caught on filters located on the summits of two Hawaiian volcanoes. His value for the rate of accumulation of extra-terrestrial nickel is $6 \cdot 5 \times 10^{11}$ gm./yr. for the Earth as a whole. If the rate of accumulation is reasonably constant over the Earth's surface, then this figure corresponds to 33×10^{-6} gm. nickel/cm.^{2} of the Earth's surface/1,000 yr.

I have recently determined the rates of accumulation of nickel and other elements in a calcareous eupelagic Atlantic equatorial core (Lamont *A* 180–76), using emission spectrography and time estimates based on radiocarbon dates made on this and neighbouring cores.

In core *A* 180–76 there are three major climatic events recorded. The estimates of the duration of each climatic zone are from the paper by Broecker, Turekian and Heezen[2]. These estimates, together with the description of each zone and the calculated rates of accumulation of nickel, are given in Table 1.

Table 1

Zone	Interval (cm.)	Climate, description and duration	Average nickel content (p.p.m.)	Rate of accumulation of nickel (10^{-6} gm./cm.^{2}/1,000 yr.)
A	0–25	The most recent warm period commencing 11,000 yr. ago	13	22
B	30–260	The last major cold period (including an interstadial period) lasting about 60,000 yr.	17	49
C	265–410	The immediately preceding major warm period lasting about 80,000 yr.	13	18

The average of the rates of nickel accumulation for zones *B* and *C*, which are of about equal duration, is 33 × 10^{-6} gm./cm.^{2}/1,000 yr., comparable to Pettersson's value for extra-terrestrial accumulation. However, this must not be construed to be a confirmation of the extra-terrestrial origin of the nickel on the sea floor. There must be a significant nickel contribution from terrestrial sources to the deep-sea since the rates of accumulation of other components, such as copper and lead, are high. If nickel follows the same pattern of supply to the sea as these elements, then a major part, if not all, of this nickel accumulated may be due to terrestrial supply. In addition, the rate of accumulation of nickel, as well as several other elements and the clay fraction, varies as a function of climate, again suggesting terrestrial control of supply. Of course, this may be a matter of redistribution in the sea rather than change in total supply. This can only be confirmed by more extensive regional determinations of accumulation-rates of deep-sea sediment components in the Atlantic.

Thermogravimetric Investigations of Peat

THE differential thermal characteristics of peat, recently reported by Mitchell[1], show an interesting correlation with results obtained in thermogravimetric studies carried out in these laboratories.

The apparatus used was a 'Stanton' thermobalance with provision for controlled atmosphere. Peat from three different sources, previously dried to approximately 10 per cent water-content for use as fuel in our experimental gas turbine, was ground and passed through a 150-mesh sieve. A 1 gm. sample was placed in a platinum crucible in the thermobalance furnace and a stream of nitrogen passed through the furnace at a velocity of 40 l./hr. Continuous recording of the weight of the sample was carried out while a rate of heating of 4° C./min. was maintained. Automatic arresting of the balance at 5-min. intervals recorded the time-scale on the weight curve. Differential curves were prepared by plotting the rate of loss of weight in mgm./min. against temperature.

The three peats used in these experiments were obtained from (*a*) Gardrum moss near Falkirk, Scotland, (*b*) Lullymore, Co. Kildare, Eire, (*c*) Altnabraec, Caithness, Scotland.

Representative differential curves obtained for these three peats are shown in Fig. 1. In all cases there is an initial evolution of water vapour in the region of 100° C., the peak occurring at a slightly higher temperature with the peats from Lullymore and Altnabraec than that from Gardrum because of the higher water-soluble contents of these peats.

Table 1. PEAKS IN DIFFERENTIAL THERMOGRAVIMETRIC CURVES OF THREE PEATS

Sample	T_1	T_2	T_3	T_2–T_1	T_3–T_2
Gardrum	350	450	525	100	75° C.
Lullymore	275	400	480	125	80° C.
Altnabraec	320	420	500	100	80° C.

T_1, First peak; T_2, second peak; T_3, third peak

Table 2. PEAKS IN COMPLETE COMBUSTION DIFFERENTIAL THERMAL CURVES (MITCHELL, *loc. cit*)

Sample	T_1	T_2	T_3	T_2–T_1	T_3–T_2
Eriophorum peat	320	420	—	100	– ° C.
Calluna peat	300	380	420	80	140° C.

T_1, First peak; T_2, second peak; T_3, third peak.

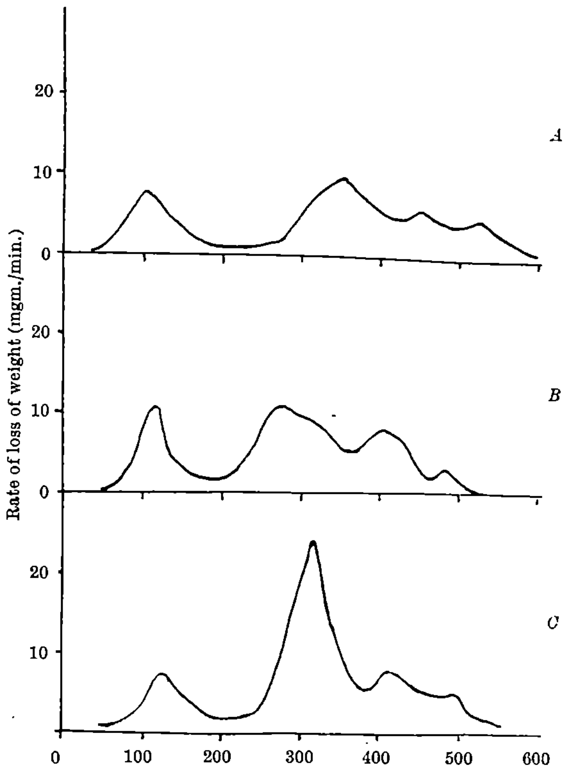

Fig. 1. Differential thermogravimetric curves of peat in nitrogen *A*, Gardrum peat; *B*, Lullymore peat; *C*, Altnabraec peat

A subsequent release of volatile matter occurs in the 250–600° C. region and exhibits a main peak followed by two smaller peaks. Although the position of the peaks varies as much as 75° C. with differing peats, their relative position in each peat is remarkably constant.

The first two peaks show a close correspondence with the two-peak system reported by Mitchell[1] in complete combustion differential thermal analysis curves (Table 2). The two main exothermic differential thermal analysis peaks must therefore result from the combustion of volatiles released at about 300° C. and 400° C. as shown by the thermogravimetric studies.

Comparative thermogravimetric studies on peat and coal have proved to be of value in predicting the burning characteristics of these fuels, and in particular in determining the degree of pre-heating necessary to release volatiles and initiate combustion.

This report is related to work done through the agency of Messrs. Ruston and Hornsby, Ltd., on behalf of the Ministry of Power, with whose permission it is now published.

Tetrahedral Co-ordination of Nickel(II)

In a recent communication[1], Katzin has interpreted the appearance of blue colour in paramagnetic nickel(II) compounds as indicative of tetrahedral co-ordination. We have recently completed the determination of the crystal structure of $Ni(en)_2(NCS)_2$ (Brown, B. W., and Lingafelter, E. C., unpublished work). This compound is blue and paramagnetic, but the co-ordination of the nickel ion is transoctahedral, with Ni—N distances of 2·10 A. to the ethylenediamine and 2·15 A. to the *iso*thiocyanate. We are also investigating the crystal structure of $Ni(en)(H_2O)_4(NO_3)_2$, another blue paramagnetic compound. Although the study is still in the early stages and all atoms have not been located, the presence of a co-ordination octahedron about the nickel atom is already clear.

Thus these two compounds show that the blue colour cannot be taken as an indication of tetrahedral co-ordination of nickel(II).

A Method for improving the Solute Selectivity of Osmotic Membranes

An examination of the results obtained with a pair of 'Ultracella' filters (fein)—manufactured by the Membranfiltergesellschaft, Göttingen—which had been used for several months in benzene at 30° C. to determine the number-average molecular weights ($\overline{M}_n$) of polymer samples, showed that during this time the membranes had become markedly less permeable to solvent. A similar observation has been made by Philipp and Bjork[1] with a gel 'Cellophane' membrane, and they attributed the phenomenon to gradual ageing of the membranes. However, with the 'Ultracella' filters (fein) closer examination of the results indicated that the change in permeability had occurred in two distinct stages both of which could be associated with attempts to measure the $\overline{M}_n$ of a sample of poly(diallyl phthalate). Experiments were therefore carried out with three other pairs of 'Ultracella' filters (fein) in order to investigate this phenomenon further.

The membranes were assembled in standard Zimm–Myerson type osmometers and before and after treatment with solutions of poly(diallyl phthalate) were characterized by (*a*) the solvent permeability, measured by the rate of fall of the meniscus in the measuring capillary under a head of 10 cm. of benzene, and (*b*) the solute selectivity, measured by the maximum osmotic head developed with a 1 per cent (w/w) benzene solution of a commercial polystyrene which has a very wide distribution of molecular weights[2].

The results in Table 1 show that in each case after treatment with poly(diallyl phthalate) the membranes became less permeable and more selective (that is, gave higher osmotic heads). Furthermore, these experiments show that the magnitudes of these effects (*a*) increased with poly(diallyl phthalate) concentration (membranes UCF/F 457/*A*1 and UCF/F 1256/4) up to a maximum concentration of about 1·5 per cent (w/v) (membranes UCF/F 1256/5), (*b*) after 16 hr. were independent of the time the membranes were in contact with the poly(diallyl phthalate) solution (membranes UCF/F 1256/4), (*c*) in the molecular weight-range 13,000–22,000 were

independent of the sample of poly(diallyl phthalate) used (membranes UCF/F 457/*A*1 and UCF/F 1256/4). This effect was also found with other types of membrane, for example, with all grades of 'Ultrafein' filters (UFF), in particular with the most porous grade, namely, 'gross', *G* (see Table 2).

Meyerhoff[3] has reported a similar phenomenon with some 'Ultracella' filters (feinst) which had been allowed to become saturated with a 0·5 per cent toluene solution of an oligostyrene (that is, a polystyrene of very low molecular weight, $\overline{M}_n = 1{,}200$). He attributed the effect to irreversible adsorption of the oligostyrene by the membrane material, an explanation similar to that suggested by Ferry[4] to account for the action of capillary-active substances in ultrafiltration techniques. A similar hypothesis would explain the results recorded here. However, in this case the adsorption of the poly(diallyl phthalate) may not be completely irreversible for in some cases a gradual increase in permeability has been observed during subsequent experiments.

The 10·1 sample of poly(diallyl phthalate) was obtained from W. Simpson of Metropolitan-Vickers Electrical Co., Ltd., and the samples *BSI* and *2H* were prepared by B. Selton of this Laboratory. I wish to thank Miss S. A. Monksfield and Miss H. M. Sankey for assistance with the experimental work. This work forms part of the research programme of the National Chemical Laboratory and is published by permission of the Director.

Detection of Certain Brominated Long-Chain Fatty Acid Esters by Gas Liquid Chromatography

EVIDENCE has recently been presented which demonstrated the effects of alteration of the chemical composition of the stationary liquid upon the resolution of the methyl esters of long-chain saturated and unsaturated fatty acids by gas-liquid chromatography[1-4]. When the adipate, glutarate and succinate polyesters of diethylene glycol were used as liquid phases, the more polar unsaturated fatty acid esters were retained on the column to a greater degree than the saturated members of similar carbon chain-length. The number and position of the unsaturated linkages appeared to be the dominating factors in determining the affinity of the component vapour for the stationary liquid. The greater the degree of unsaturation beyond the 9,10 position in the fatty acid ester molecule, the slower was the movement of the substance down the column. This effect appeared to be modified somewhat by the occurrence of a double bond closer to the carboxyl group, that is, before the 9,10 position, which tended to hasten the emergence of the compound from the column. Although the polyesters were much more efficient as stationary liquids than the comparatively non-polar 'Apiezon' and silicone greases[5,6] for achieving separations of saturated and unsaturated fatty acid esters, when samples of fatty acid esters of unknown composition were analysed by gas-liquid chromatography, the possible presence of esters of branched-chain acids, odd-numbered acids, and unusual mono-, di- and poly-unsaturated acids still made difficult the positive identification of the individual components on the basis of comparative retention times and volumes.

Bromination of a mixture which has been previously analysed chromatographically and then re-running the brominated sample has been a common technique for determining the presence of compounds containing double bonds. Bromine adds to the double bonds to form a dibromide, tetrabromide, hexabromide, etc., depending upon the degree of unsaturation. In the early methods which employed columns containing 'Celite 545' coated with 'Apiezon' at 200° C. for the determination of fatty acids by gas-liquid chromatography, detection of brominated components was not noted[6]. Under these conditions, the disappearance of certain compounds following bromination and rechromatography was indicative of those substances in the original mixture that contained unsaturated linkages. The chain-length and number of double bonds were estimated according to the comparative retention times and volumes. The position of the double bonds was then determined by additional oxidative procedures[7].

A study was undertaken in this laboratory in an effort to detect by the gas-liquid chromatographic technique the presence of brominated fatty acid esters on columns containing highly polar polyesters as liquid phases. A mixture containing 34 per cent of methyl stearate and 66 per cent methyl oleate was resolved on a chromatographic column 8 ft. long containing 60–80 mesh 'Celite 545' coated with 10 per cent glutarate polyester of diethylene glycol at 205° C. An ionization chamber was used as a detection device. The rate of flow of argon was 60 ml. per min. The stearate and oleate bands had corrected retention volumes of 570 ml. and 645 ml. respectively. Aliquots of the same mixture were brominated by several procedures and then reapplied to the same column. A chromatogram of the brominated mixture revealed the presence of three peaks in addition to that of the unchanged stearate (Fig. 1). It was unlikely that any of the peaks represented unbrominated oleate since their retention times were longer than that of oleate. This was further verified by rebromination of the mixture which when re-chromatographed did not alter the appearance of the chromatogram.

The retention volumes and percentage composition of the three new components are presented in Table 1. By altering the operating parameters, the largest peak (No. 3) was found to contain another component from which it was partially resolved.

It should be noted that other mono-unsaturated acid esters yielded volatile brominated products which could be detected under the operating conditions already defined of the gas chromatographic technique. However, when methyl linoleate was brominated and the products analysed, distinct peaks were absent, although after 13 min. a shift in the

* Methyl stearate, unchanged by bromination.

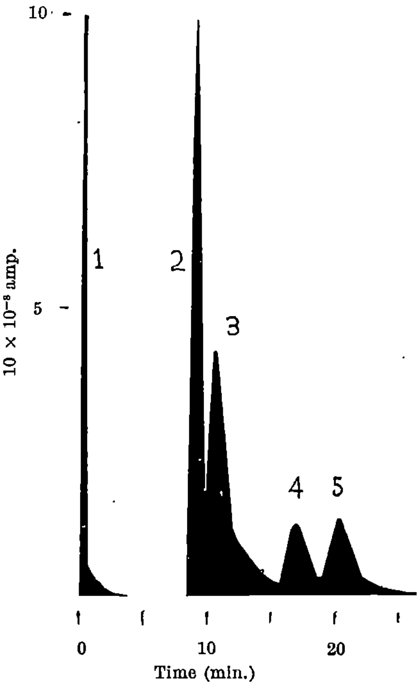

Fig. 1. Gas-liquid chromatographic analysis of a brominated mixture of methyl stearate (34 per cent) and methyl oleate (66 per cent), using an 8-ft. column containing 60–80 mesh 'Celite 545' coated with 10 per cent polydiethylene glycol glutarate at 205° C. Argon flow-rate, 60 ml./min. An ionization chamber was used as a detection device. 1, Solvent peak; 2, stearate; 3, 4 and 5, brominated products

base line was noted which continued for another 15 min. (The retention time of methyl linoleate under these conditions was 13 min.)

The exact chemical nature of the components found in the brominated mixtures is obscure. Although the materials appeared to be saturated when applied to the column, it is conceivable that dehydrobromination to yield mono-bromo-mono-unsaturated or doubly unsaturated compounds could occur during passage down the column. It is significant that even though side reactions may occur during or after bromination these nevertheless appear to be quantitatively reproducible. No differences were noted when (*a*) the bromination procedure was carried out by using pyridine sulphate dibromide in acetic acid or free bromine (1 per cent) in ether, and (*b*) the excess bromine was destroyed before removing the solvent or evaporated off along with the solvent.

The major brominated peak (Fig. 1, No. 3) is probably methyl 9,10-dibromostearate. The rapid emergence of this compound from columns containing polyesters as liquid phases is in sharp contrast to the behaviour of this substance when the 'Apiezon' greases were employed as stationary liquids. In these latter circumstances, detection of this material was noted only when the columns were operated[8] at 275° C. It cannot be determined at the present time whether or not the double peak (Fig. 1, No. 3) represents *d*- and *l*-dibromostearate, the anticipated product of bromination of a *cis* double bond.

When methyl elaidate was brominated, a similar pattern with much broader peaks was seen. Splitting of the major peak was not achieved, but this was no reason to believe it was homogeneous even though the *meso* dibromide is the expected product.

Alleged Susceptibility of Sulphydryl Enzymes to Ionizing Radiation

SINCE the work of Barron *et al.*[1–3] it has been generally assumed that sulphydryl enzymes, in contrast to enzymes not requiring free SH-groups for their activity, are exceptionally susceptible to the indirect action of ionizing radiation. This view, which has profoundly influenced radiobiological thinking during the past decade, is not supported by recent experiments in this laboratory. In the present communication results are presented to show that the sulphydryl enzymes muscle glyceraldehyde-3-phosphate dehydrogenase and yeast alcohol dehydrogenase are inactivated by X-rays with about the same ionic yield as various non-sulphydryl enzymes.

Crystalline muscle glyceraldehyde-3-phosphate dehydrogenase (specific activity $3 \cdot 8 \times 10^5$ as defined by Velick[4]) and crystalline yeast alcohol dehydrogenase (specific activity $1 \cdot 8 \times 10^5$ units per mgm. protein[5]) were prepared[4,5]. In both cases the enzyme activity was determined spectrophotometrically under conditions of substrate and coenzyme concentrations which are optimal for measuring the activity of the apoenzyme[3,4].

It appears from Table 1 that when irradiated in dilute aqueous solutions equilibrated with air, both enzymes were inactivated by X-rays with ionic yields of about 0·02. These yields fall in the same range as those previously reported for a number of non-sulphydryl enzymes[1,2,6–8], providing evidence that glyceraldehyde-3-phosphate dehydrogenase and alcohol dehydrogenase are not particularly sensitive to the indirect action of ionizing radiation. The results stand in striking contrast to the reports by Barron *et al.*[1–3] that these enzymes are inactivated with ionic yields of about 1. Furthermore, the claim that glyceraldehyde-3-phosphate dehydrogenase can be partly reactivated by addition of reduced glutathione after irradiation[1] could not be confirmed.

The results here reported do not constitute evidence against the view that protein SH-groups are highly susceptible to ionizing radiation. Since the most active alcohol dehydrogenase preparations contain up to 36 titratable SH-groups[9], the present results with alcohol dehydrogenase are consistent with the assumption that in solution each accessible SH-group is inactivated with an ionic yield of about 1. A linear relationship is known to exist between the number of free SH-groups (in the interval 4·5–36) and the enzyme activity[9]. The present finding that aged alcohol dehydrogenase preparations with lower specific activities are inactivated with unchanged ionic yield (Table 1) suggests that the disappearance

Table 1. INACTIVATION OF GLYCERALDEHYDE-3-PHOSPHATE DEHYDROGENASE (GAPDH) AND ALCOHOL DEHYDROGENASE (ADH) BY X-RAYS

Irradiation conditions: 70 μgm. glyceraldehyde-3-phosphate dehydrogenase per ml. 0·07 *M* phosphate buffer, *p*H 7·4 (5×10^{-7} *M*); 45 μgm. alcohol dehydrogenase per ml. 0·01 *M* phosphate buffer, *p*H 7·4 (3×10^{-7} *M*). The enzyme solutions, equilibrated with air, were irradiated at 3° C. Irradiation factors: 4 m.amp., 200 keV., 0·5 mm. copper filter

* 1 r. is assumed to give 3×10^{-9} *M* ion-pairs in solution

of free SH-groups accompanying the fall in activity[9] does not influence the ability to capture radicals of the sulphur atoms in question. Probably the ageing involves the conversion of SH- to SS-groups, which are likewise known to be highly susceptible to the indirect effect of ionizing radiation.

A complete report of this work will appear elsewhere.

Phylogenetic Distribution of Acid Phosphatase inhibited by (+)-Tartrate

AN interesting stereo-specific inhibition by (+)-tartaric acid of certain acid phosphatases of human origin has been reported by Abul-Fadl and King[1]. We have had occasion in our work to note, as certainly many others must have, that inhibition by (+)-tartrate is a property which extends to other mammalian phosphatases. On the other hand, we have observed that none of a number of acid phosphatases present in crude extracts obtained from higher plants was preferentially inhibited by this substance. On further investigation of acid phosphatases of both plant and animal sources, we have consistently found the property of specific inhibition by (+)-tartrate to be associated with those organisms which are universally accepted as members of the animal kingdom, whereas those which are customarily regarded as plants invariably did not possess such an enzyme. In view of this sharp division, it became of interest to examine the protists, and these results are shown in Table 1, along with those obtained with *bona fide* 'plants' and 'animals'. Only a few examples of the many which are available for the higher plants and animals are given. We have listed all the lower forms of plants and animals and of the protists which we have been able to test (except a number of bacteria, all of which were negative).

Table 1. INHIBITION OF BIOLOGICAL ORGANISMS BY (+)-TARTRATE. The reaction mixtures consisted of 2 ml. of *p*-nitrophenyl phosphate (0·015 *M* in 0·1125 *M* acetate buffer, *p*H 5·0), 0·5 ml. of inhibitor, and 0·5–2·0 ml. of enzyme in a final volume of 4·5 ml. The tests were carried out with the aqueous extracts of the various organisms, essentially as described previously (ref. 2)

Source	Per cent inhibition by tartrate	
	(+)-isomer 0·02 *M*	(−)-isomer 0·02 *M*
Monezia expansa	51	10

Thermoactinomyces sp.	20	20
Streptomyces griseus	0	0
Actinomycetes sp.	0	0

Several points of interest may be noted. In no case have we encountered an exception to the rule that 'unequivocal' plants lack, and animals possess, phosphatases inhibitable by (+)-tartrate. The euglenids are like the animals; the superficially similar chlamydomonads are like the plants. *Tetrahymena pyriformis*, a true protozoan, is, by this criterion, animal-like. All the bacteria tested, including the morphologically complex Actinomycetes, are plant-like. So also are *Saccharomyces cerevisae*, an ascomycetous yeast, and *Sporobolomyces*, which forms ballistospores. Among the Phycomycetes, it was found that *Rhizopus* and *Mucor* species do not possess the inhibitable phosphatases, whereas *Phytophthora*, *Pythium* and *Blastocladiella* do. The crude acid phosphatase of the slime mould, *Physarium polycephalum*, was very sensitive to (+)-tartrate. All the species of Ascomycetes and Basidiomycetes tested contained the inhibitable enzyme.

We do not wish to emphasize unduly the 'animalness' of the lower organisms; we realize that the dichotomy of the plant and animal kingdom may be no more than a man-made division. Neither do we wish to presume that there are only two main phylogenetic trunks. Nevertheless, we do direct attention to the possible utility of inhibition by (+)-tartrate as a taxonomic device, even if it may not necessarily hold any profound implications for the moot problem (to some biologists) of how one tells the plants from the animals.

A word of caution needs be expressed. In all cases only crude extracts were tested. Not all animal phosphatases are inhibited by (+)-tartrate, and it should be noted that a concentration of 0·02 *M* (+)-tartrate, which is sufficient to cause a 93 per cent inhibition of the prostatic acid phosphatase, a source of acid phosphatase fairly homogeneous with respect to a single phophomonoesterase, did not cause a similar degree of inhibition with other animal phosphatases. With the animal preparations shown, it is possible that these do contain some non-inhibitable phosphatases as well. It is not impossible that extracts which we report as non-inhibitable do contain quantities of phosphatases inhibitable by (+)-tartrate too small to be significant in our assay. The possibility that the inhibition was due to non-specific ionic effects or to sequestering of essential cations was controlled by the use of (−)-tartaric acid.

We are greatly indebted to our many biologist colleagues at the University of California in Los Angeles, the University of Michigan, Michigan State University, and Purdue University for many of the organisms used in this work.

Occurrence of α-Picoline in Plants

WILKINSON[1] has recently directed attention to the occurrence of α-picoline in the leaves of *Rumex obtusifolians*, which is believed to be the first record of the presence of this substance in plant material.

It is perhaps of interest to refer to some earlier investigations on the occurrence of a fluorescent alkaloid in rye-grass (*Lolium perenne* L.), in which was also recorded the isolation of other less-complex nitrogenous substances including a picoline-like compound[2,3]. This compound was not completely identified; but its absorption spectrum and empirical formula were indistinguishable from those of a picoline. However, close comparisons between the melting points and mixed melting points of the picrates and mercurichlorides with those of the α, β and γ picolines failed to identify the base, as did comparisons with the melting points of the fully hydrogenated derivatives. Moreover, no acidic products were obtained during oxidation under conditions which resulted in the formation from α-, β- and γ-picolines of the corresponding acids.

We have not had a further opportunity to investigate the nature of this base, but we are now prompted to recall our findings in the hope that these earlier results will be clarified by other workers.

Fermentation of Glucose by *Chlorella vulgaris*

IT has been shown recently that the chief products of glucose fermentation by *Chlorella vulgaris* (Pearsall's strain) are acetic acid, lactic acid, hydrogen and a little carbon dioxide[1]. It was of interest to study the fermentation of glucose labelled with carbon-14 in particular carbon atoms since, from a determination of the distribution of carbon-14 in the molecules of the products, something can be learnt of the fermentation pathway.

2 μc. and 1·5 μmoles glucose were supplied to 40 mgm. dry weight *Chlorella* suspended in 2 ml. 0·02 *M* phosphate, *p*H 7·0, in Warburg flasks which were filled with oxygen-free nitrogen; the flasks were shaken at 25° C. in darkness. The radioactive glucose was supplied by the Radiochemical Centre, Amersham, and was labelled in either the 1, 2 or 6 carbon atoms or was uniformly labelled. Carbon dioxide was collected in sodium hydroxide in the centre-wells of the Warburg flasks. When fermentation had ceased, the centre-well solutions were withdrawn and the carbonate precipitated and counted as barium carbonate after the addition of 1·5 mmoles sodium carbonate as carrier. The cell suspensions were removed, 1·5 mmoles acetic acid and 1·5 mmoles lactic acid added to each and the cells killed by heating to 100° C. The cells were extracted with hot water and the extracts run through columns of 'Zeokarb 215' to remove amino-acids. Acetic acid was then removed by steam distillation. Lactic acid in the residue was obtained either by ether extraction or by separation on a silica-gel column[2]. The acetic and lactic acids were then degraded[3] and their carbon atoms recovered as carbon dioxide. All counts were made on barium carbonate samples of infinite thickness. The distribution of carbon-14 is shown in Table 1.

Table 1. THE DISTRIBUTION OF CARBON-14 IN THE ACETIC ACID AND LACTIC ACID PRODUCED DURING THE FERMENTATION OF 1·5 μMOLES AND 2 μC. OF GLUCOSE-1-^{14}C, GLUCOSE-2-^{14}C OR GLUCOSE-6-^{14}C BY *Chlorella vulgaris*

The figures show the percentage of the total radioactivity contributed by each carbon atom in the molecules of the products. The last column shows the radioactivity in the carbon dioxide produced by the fermentation

Glucose supplied	Acetic acid CH_3—COOH		Lactic acid CH_3—CHOH—COOH			C.p.m. in carbon dioxide
Glucose-1-^{14}C	98·5	1·5	81·0	0·3	18·7	589
Glucose-2-^{14}C	1·7	98·3	0·7	85·9	13·4	363
Glucose-6-^{14}C	98·2	1·8	87·0	0·1	12·9	335
Uniformly labelled	—	—	—	—	—	1,071

The results show that the 1- and 6-carbon atoms of glucose are converted to the CH_3- carbon of lactic and acetic acids while the 2-carbon atom is converted to the —CHOH— carbon atom of lactic acid and to the —COOH carbon of acetic acid. This is the labelling pattern which would result if glucose were split by the Embden–Meyerhof–Parnas glycolysis reactions into two C_3 fragments which were either converted to lactic acid or decarboxylated to a precursor of acetic acid. In agreement with this view is the fact that most of the carbon dioxide produced during the fermentation appears to arise from the 3- and 4-carbons of glucose. The yield of carbon-14 dioxide from uniformly labelled glucose is much greater than that from the 1, 2 or 6 labelled sugar. If one assumes that the contribution of the 5-carbon of glucose to the carbon dioxide production is equal to that of the

2-carbon, the relative contributions of the glucose carbons to the carbon dioxide production can be calculated as (per cent): C_1, 9·2; C_2, 5·7; C_3 and C_4 together, 74·2; C_5, 5·7; C_6, 5·2. Nevertheless, all the glucose carbons contribute to the carbon dioxide production and the 1-carbon contributes more than the 6-carbon. Consequently, reactions other than the Embden–Meyerhof–Parnas glycolysis ones must be involved to some extent.

The labelling of the carboxyl group of lactic acid is noteworthy. It is probably a result of carbon dioxide fixation, which is known to occur during glucose fermentation by *Chlorella*[1].

Isolation of Oxo-Steroids under Neutral Conditions

Girard's reagent *T* (trimethylammonium hydrazide chloride)[1] is extensively used for the separation of oxo-steroids from other steroids and particularly for purification of 17-oxo-steroids in extracts of acid- or enzyme-hydrolysed urine[2]. The method employed usually involves dissolving the material and Girard reagent in glacial acetic acid, and either heating the mixture for periods of up to 1 hr. or allowing it to stand overnight at room temperature. During this procedure destruction of labile steroids and some acetylation of hydroxy-steroids tend to occur (ref. 3 and unpublished observations).

Before extraction of non-ketonic material from the water-soluble Girard complex the acetic acid is nine-tenths neutralized by addition of strong alkali. The heat evolved, which may be deleterious to some steroids, is counteracted by carrying out the neutralization under ice-cold conditions. After extraction of the non-ketonic material the Girard complex is hydrolysed by taking the solution to *p*H 1 and allowing it to stand for 2–48 hr. Under these conditions destruction of labile steroids may occur.

Recently, Teitelbaum[4] has described an elegant modification of the method for application to labile aldehydes and ketones such as citral, benzaldehyde, etc., which are extensively destroyed by the old method. The new method involves forming the Girard complex in ethanolic solution in the presence of cation exchange resin ('Amberlite *IRC*50'), and then splitting the complex by adding excess aqueous formaldehyde. Thus many of the disadvantages of the old method have been avoided, and also the new method is simpler and less time-consuming.

The applicability of the new method to oxo-steroids has therefore been investigated. In these exploratory experiments the steroids used were progesterone (I) and 21-hydroxy-5β-pregnane-3 : 20-dione (II) (pregnanediolone). The steroid (10 mgm.) was dissolved in 1 ml. ethanol and 20 mgm. Girard reagent *T* and 5 mgm. 'Amberlite *IRC*50' were added. The mixture was heated under reflux for 1 hr., and after addition of 10 ml. water was extracted 3 × with 10 ml. solvent (ether for I ethyl acetate for II). The amount of steroid appearing in this non-ketonic fraction was then determined. After addition of 2 ml. of 40 per cent formalin, the aqueous solution of the Girard complex was allowed to stand overnight. Extraction with solvent then yielded the ketonic fraction. For comparison 10 mgm. steroid were also treated by the old method[2].

The results presented in Table 1 show that the new method is more effective than the old.

Table 1

Steroid	Percentage recovery from: (*a*) Non-ketonic fraction	Percentage recovery from: (*b*) Ketonic fraction
Progesterone:		
Old method	0·5–1·5	82–86
New method	0·4–1·0	92–96
21-Hydroxy-5β-pregnane-3 : 20-dione:		
Old method	< 1	80–82*
New method	< 1	90–95

* Approximately 10 per cent of product was acetylated at C-21.

Further experiments were carried out with progesterone to determine the rate of formation of the Girard complex at room-temperature using the new method. The results are shown in Table 2. It can be seen that complex formation is fairly rapid at room temperature, and is virtually complete in 7 hr.

Table 2

Time (hr.)	0·25	0·5	1	2	3	7	24
Progesterone in non-ketonic fraction (per cent)	84	76	55	15	10	3	1

The rate of splitting of the Girard reagent – progesterone complex by formaldehyde was also investigated, and the results are shown in Table 3.

Table 3

Time (hr.)	0·1	1	7	17	24
Progesterone in ketonic fraction (per cent)	40	76	95	98	98

Thus it is apparent that this new method of using the Girard reagent is applicable to steroids, and in view of the mild conditions employed it is recommended for use, particularly in work with labile steroids.

I wish to acknowledge gifts of steroids from Drs. C. L. Hewett (Organon) and G. D. Laubach (Pfizer).

Electroencephalograph Correlates of Ammonium Carbonate Intoxication in the Rat

In the literature[1,2] relating to ammonia intoxication in man and animals, the basic assumption has been that ammonia exerts a primary chemical action on brain cells. However, of the two papers in the animal experimental group on the effect of ammonia on the functioning of the central nervous system using electroencephalography, Marsan *et al.*[3] interpreted the transiently decreased electrical activity observed in the dog's brain as a direct consequence of general cellular anoxia due to an embarrassed cardiac output; and Torda[4] believed her results indicated an increase in cerebral activity because of the paroxysmal slow waves following the intraperitoneal injection of ammonium chloride. We have demonstrated that under proper conditions of administration of ammonium salt, a primary cortical neuronal response may be achieved, as evidenced by a decreased electric output.

11 per cent (w/v) of ammonium carbonate (reagent grade) in glass-distilled water was administered intravenously in divided doses of 27–220 mgm./kgm. of body-weight to segregated female Sprague–Dawley rats weighing 239–300 gm. A total of 63 experiments was performed. All electrode implantations, vessel and tracheal cannulations were performed under ether anæsthesia. Some animals were later immobilized by tubocurarine intravenously administered. In these cases, the curarizing material was injected slowly and titrated to the level of either minimal electroencephalographic change, or to the cessation of respirations, whichever appeared first. Oxygen was administered by an intermittent positive pressure system. The electroencephalograph derivations were obtained by means of small brass wood-screws placed in the homologous bilateral frontal and occipital regions of the skull. Variations in blood pressure were transduced with a Statham type 23 *A* strain-gauge, suitably connected to the abdominal aorta. The electrocardiograph was derived from clips attached to the skin behind the forepaws. All electrical measurements were made with Offner 141 amplifiers and dynagraph records. The ammonium carbonate was administered intravenously over an interval of 10–20 sec., in doses of 27–55 mgm./kgm. body-weight.

Section 4 of Fig. 1 is representative of the control electroencephalograph, electrocardiograph and blood pressure. In section 5 with the administration of ammonium carbonate in two successive doses of 55 mgm./kgm. each, a decrease in amplitude of the electroencephalograph was observed within 20 sec.; no substantial alteration in the heart function was recognized. Section 6 shows recovery of the brain activity to its control type. This section also shows the electrical activity at the end of the third administration of the chemical. Within 1 min. after this latter injection, section 7 again illustrates the decrease in amplitude of the output of the electroencephalograph. Array 8 shows the electroencephalograph activity 1 min. after the preceding; it is observed that the output becomes almost isoelectric; the heart function shows no evidence of impairment. Approximately 10 min. after the preceding section of waves (section 8), recovery again took place in section 9. Section 10 shows tracings, 1½ min. after the injection of only 55 mgm. of ammonium carbonate per kgm. body-weight. The isoelectric output is evident. We have accomplished such recycling repeatedly. Clinically the animals remain in a state of unresponsiveness during the interval of diminished electrical output; they can in no way be considered 'alerted'.

Ulshafer[2] showed that rats injected with ammonium carbonate had a consistent diminution in the acetylcholine-level of the brain as compared with controls. Larger doses of the chemical decreased the measured amount of acetylcholine of the brain. He suggested that the decreased brain acetylcholine resulted from the action of the ammonium ion in the conversion of glutamic acid to glutamine. We believe, therefore, that the electroencephalographic changes demonstrated are consistent with, and an expression of, a reduced acetylcholine content of the brain.

In conclusion, our material demonstrates that ammonium carbonate has a direct action on the central nervous tissue of the rat. This action is to reduce spontaneous electrical output.

Dependence of Latent Period in Muscle on Strength of Stimulus

The so-called latent period, which includes latency relaxation, has an important bearing on theories of excitation coupling. It is surprising then that systematic studies[1,2] of this phenomenon do not mention the role of the stimulus. The reason is that, with the frog sartorius, increasing strength of stimulus above twice the threshold value apparently produces no significant effect on the latency, while below this value the effects may conceivably be dismissed as due to 'recruitment of fibres'. Even here, however, latency relaxation increases and may reach as much as 1 per cent of tetanus tension at ten times threshold field-strength.

In my experiments, to eliminate conduction-time effects, stimulation is by transverse field—an arrangement introduced by Brown and Sichel[3] in their study of single sartorius fibres. It is noteworthy that the records of these authors (their Fig. 6, p. 324) show clear evidence of decrease of latent period with increase of field, as well as increase of twitch tension.

These effects can be seen in whole muscles other than the sartorius in much more striking form. Fig. 1 shows a result obtained with a muscle similar to toad sartorius. With increasing field three effects occur in

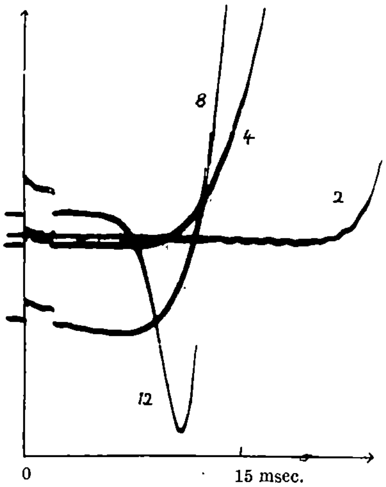

Fig. 1. Latent period in r. capitis-collique of turtle (*Chrysemys pictans*) at 0° C. Ordinate: tension. Figures refer to stimulus strength in V./cm. Duration of stimulus, 1·5 msec. (shown superimposed on tension record)

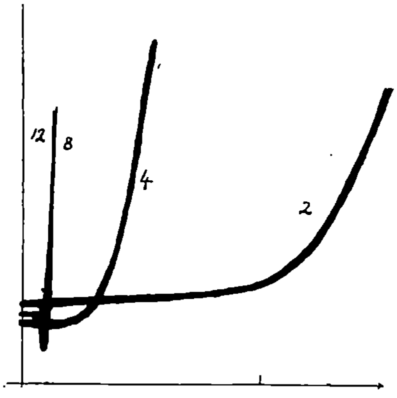

Fig. 2. Latent period in r. penis of turtle (*Pseudemys elegans*), 0° C. Duration of stimulus, 3 m.sec. Note that latency relaxation begins at 8 V./cm. while the record for 12 V./cm. is virtually superimposed on this

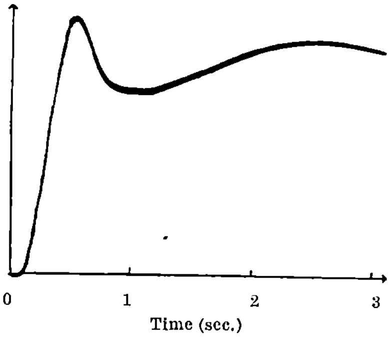

Fig. 3. Subsequent isometric development of tension for curve of Fig. 2 for 8 V./cm. Second peak corresponds to normal twitch as obtained from a propagated action potential

sequence : (1) decrease of latent period ; (2) increase of initial rate of development of tension ; (3) onset of latency relaxation.

The same is true for a slow tonic muscle (Fig. 2) where, however, effects 1 and 2 are much greater and occur simultaneously. In fact the effect 2 is so great as to show a spike of tension (Fig. 3), reminiscent of a 'quick stretch' effect[4], superimposed on the normal twitch response. By varying the duration of the stimulus one finds that the time constant for the process involved is about 1 msec.

These observations are consistent with the view that by transverse stimulation we can drive the membrane to greater amplitudes than the normal propagated action potential, thereby accelerating a process precursor to activation.

Lysins and Agglutinins in Normal and Lymphomatous Mouse Tissue

LYSINS and agglutinins have been extracted from normal mouse tissues, and often in much higher concentration from the mammary adenocarcinomas of the female *C3H* mouse. Three methods have been used for extraction[1–4] : (*a*) extraction of minced-up tissues in saline (1 per cent sodium chloride), (*b*) 'pre-incubation' of homogenized tissue at 37° C. in saline for 12–18 hr., which results in the separation of a yellow hæmolytic fluid, and (*c*) extraction with ether, which gives an ether-soluble 'soap-like' lytic material and also a lytic material insoluble in cold ether ('lysolecithin'). These methods and their results have been reviewed by Ponder[3] in relation to a background which begins with the work of Metchnikoff in 1893. Probably only method (*a*) is of real value for demonstrating tissue lysins and inhibitors ; the other two methods are to some extent unreliable since they involve the splitting of pre-existing complexes.

Recently, Pirofsky[5] has obtained lysins and agglutinins, detected by trypsinized red cells, from the white cells of human leukæmia (7 chronic lymphatic, 4 chronic myelogenous and 2 acute leukæmias). Many, but not all, of the properties of these extracted substances are like those of extracts of mouse tissues and tumours, but the extraction media used are different (30 per cent sucrose, 11·5 per cent sodium chloride and 0·82 per cent sodium chloride), and neither the lysin nor the agglutinin was found to be soluble in alcohol or ether. They are not related to the β-hyaluronidase described by Leroy and Spurrier[6], and a non-dialysable substance in plasma inhibits their action.

This communication is concerned with the lytic and agglutinating properties of fresh homogenized lymph glands from normal and leukæmic (better termed lymphomatous) *AKR* mice. The mice are killed and the lymph nodes dissected out immediately ; in the lymphomatous mouse, the thymus may be large and infiltrated with lymphoma cells. In the normal mouse, the tissue which is homogenized is the lung. Blood is withdrawn from the heart. The nodes (normal and lymphomatous as determined later by section) are homogenized for 5 min. in a 'Vir-Tis' homogenizer moving at 35,000 rev./min., the proportion used being 200 mgm. of tissue in 1 ml. of saline. Centrifuging for a few minutes removes gross particles, and the homogenate is diluted with Michaelis's buffer at *p*H 7 in powers of 2. The red cells obtained from the heart are washed three times with saline, packed, and 0·1 ml. suspended in 10 ml. of saline. They are not trypsinized. A volume of

Table 1

Tissue	1 hr.	2 hr.	3 hr.
Normal	3, 4	2, 3, 4	2, 3, 4
Normal	0	0	0
Normal	0	0	2
Leukæmic	0	3	3, 4
Leukæmic	2, 3	2, 3, 4	2, 3, 4, 5
Leukæmic	2, 3, 4	2, 3, 4, 5	2, 3, 4, 5

0·1 ml. of the dilute red-cell suspension is added to each tube containing 0·2 ml. of diluted homogenate. The tubes are placed in a water-bath at 37° C., and are observed for lysis or agglutination for 3 hr. Controls are included.

Table 1 is self-explanatory. Lysis (complete) and agglutination are expressed in terms of the tubes in which they occur; for example, lysis 3–4 means that complete lysis occurs in tubes 3 and 4 of the series of dilution of the homogenate in powers of 2. Tubes containing higher concentrations of the homogenate, for example, tubes 1 and 2, always show agglutination, whereas tubes containing smaller concentrations of the homogenate than those which produce lysis, for example, tubes 5, 6, etc., show neither lysis nor agglutination. So far as lysis is concerned, each series of dilutions shows a zone phenomenon like that described for extracts of mouse carcinoma[4]. The lytic phenomenon is dependent on *p*H, occurring in the highest dilutions of the homogenates at a *p*H between 7 and 8.

Lytic material can be extracted by adding to 1 volume of the homogenate either 3 volumes of hot alcohol or the same amount of hot ether or of cold (2° C.) ether, shaking, filtering, evaporating the alcohol or ether to dryness under a fan at room temperature, and taking up the dry residues with Michaelis's buffer at *p*H 7. This rapid method of extraction is preferable to the longer method described by Ponder[2], particularly when only small amounts of homogenate are available. If Pirofsky is right in saying that these methods fail to extract lytic material from human leukæmic cells, there is a demonstrable difference between the lytic substances of mouse tumours, mouse leukæmia and human leukæmia. Unfortunately, the extraction methods were devised to be applied to blood and to pre-incubated tissues, including mouse tumours; the lytic material is bound to proteins, from which it may be split off by the extraction. There is no reason for thinking that this lytic material is the same as that in homogenates which have not been pre-incubated and extracted, which sometimes produce lysis in less than an hour. The concentration and nature of the latter material are still unknown, except that it too seems to be associated with inhibitors (agglutinins), and that it is found in normal as well as malignant and leukæmic tissues of the mouse, the concentration in normal tissues, however, usually being small.

Levels of Serum Cholesterol in Obese Mice

CHOLESTEROL-levels have been the object of considerable attention lately because of their possible relation to degenerative diseases, atherosclerosis in particular. In a number of experiments hypercholesterolæmia has been produced in experimental animals by adding cholesterol to the diet and by making other dietary changes.

It may be useful to direct attention to the fact that spontaneous hypercholesterolæmia in the absence of any cholesterol feeding has been observed under three conditions in the mouse. During the past few years, this laboratory has been engaged in a study of the etiology of the various forms of obesity using the mouse as the experimental animal[1,2]. Hypercholesterolæmia was observed to be invariably present in the hereditary obese hyperglycæmic syndrome, in the obesity due to the grafting of tumours secreting adrenocorticotrophic hormone and is also seen in female yellow obese mice. By contrast, hypercholesterolæmia is not seen in goldthioglucose-hypothalamic obesity (nor, for that matter, in the hypothalamic obesity induced by the use of stereotaxic instruments). It was thought useful to compare results pertaining to serum cholesterol-levels in various forms of obesity in the mouse which have been published only in fragmentary form.

Table 1 summarizes serum cholesterol values determined by the Kendall–Abell method in four types of obese mice[3]. It is readily seen that the obese-hyperglycæmic mice and obese mice with tumours secreting adrenocorticotrophic hormone have serum cholesterol-levels about twice as high as those of their respective controls. These two types of obesity are representative of what has been called 'metabolic' obesity, namely, those types of obesities in which the hyperphagia is secondary to metabolic disorders of fat and carbohydrate metabolism. Such animals are characterized by increased lipogenesis and cholesterologenesis, even under fasting conditions[4,5]; by the retention of a high body-fat content even when the animals are reduced to the control weight

Table 1. SERUM CHOLESTEROL LEVELS IN FOUR TYPES OF EXPERIMENTAL OBESITY IN MICE

Results for the first three types of obese mice are for males and females pooled as there is no sex difference with respect to serum cholesterol levels

Types and No. of mice	Body-weight		Serum cholesterol (mgm./100 ml.)	
	Range (gm.)	Average and stand. deviation	Range (gm.)	Average and stand. deviation
Goldthioglucose:				
Hypothalamic obese (25)	42–63	53 ± 12	101–149	125 ± 24
Normal Swiss controls (25)	24–32	29 ± 3	71–153	112 ± 41
Obese hyperglycæmic				
Obese (20)	49–62	55 ± 18	134–220	192 ± 24
Normal *V*-stock controls (30)	21–33	27 ± 6*	74–116	106 ± 10*
Adrenocorticotrophic hormone†				
Obese (13)	22–32	28 ± 4	121–133	127 ± 6
Normal LAF_1 controls (14)	24–30	27 ± 3	66–74	70 ± 4*
Yellow mice:				
Obese (17)	46–56	51 ± 5	116–212	164 ± 48
Normal controls (black) (14)	32–42	37 ± 5*	153–227	190 ± 37
Females:				
Obese (17)	48–60	54 ± 6*	153–227	190 ± 37
Normal controls (14)	32–36	34 ± 2*	114–168	141 ± 27*

† Mice of LAF_1 strain grafted with pituitary adrenocorticotropin-secreting tumours.

and by other enzymatic, endocrine, metabolic and behavioural idiosyncrasies. By contrast, goldthioglucose mice, which exemplify 'regulatory' obesity, namely, that type of obesity in which the hyperphagia is due exclusively to a lesion in the higher nervous centres controlling appetite, have normal levels of serum cholesterol. Regulatory forms of obesity are characterized by the fact that rates of lipogenesis and cholesterologenesis are brought back to normal levels when hyperphagia is eliminated and by the fact that body composition goes back to normal when weight is reduced to control levels.

The cholesterol picture of the yellow mice parallels the more complex sex-linked situation observed in these animals[6]: the female mice, which are characterized by much greater adiposity and rates of lipogenesis and cholesterologenesis higher than normal when fasted (unpublished work) are also characterized by high levels of cholesterol.

It thus appears that obese mice of different types suitably compared may offer particularly good material for the study of factors influencing the concentration of serum cholesterol and for the study of the influence of this on the development of lesions of atherosclerosis.

Toxicity of a Cholinesterase Inhibitor to the Hibernating Hamster

METABOLIC activity is profoundly altered in the hibernating animal, as compared with that in the normal. Evidence is also available that under hibernating conditions nervous function in certain species can be affected[1]. Consequently it was of considerable interest to determine the toxicity of a ganglionic blocking agent to animals under the abnormal metabolic conditions produced by hibernation. The toxicity of the cholinesterase inhibitor O,O-diethyl-S-2-diethylaminoethyl phosphonothiolate[2] has been determined in the nornal and hibernating hamster by the intraperitoneal route.

Hibernation was induced by keeping the animals in the cold. A group of one hundred male animals weighing between 100 and 130 gm., were kept in individual cages in the cold room. The temperature was adjusted to ÷ 10° C. for the first week, then lowered to + 5° C. for the remainder of the experimental period. Animals were allowed 8 hr. of artificial light a day and disturbed as little as possible. Hibernation was induced in some animals as early as the sixth week and in others as late as the fifteenth week, by which time a total of forty animals had gone into hibernation. Inspection was carried out twice a day and toxicity determinations made 24 hr. after hibernation was first observed.

Handling of the animal, necessary for (intraperitoneal) injection, even if done with the greatest of care, initiates the waking mechanism, so that within a few hours the animal is active and apparently back to normal. Thus, strictly speaking, the results on toxicity refer to animals in the intermediate state between undisturbed hibernation and normal activity. Nevertheless, the rapid action of the inhibitor ensures that toxic symptoms are well established before a return to normal activity has been accomplished.

For each toxicity determination the inhibitor was made up afresh in anhydrous propylene glycol at a concentration of 1 mm.^{3}/ml., and an 'Agla' microsyringe was used for injection.

The *LD*50 determined on a normal group of 140 hamsters and calculated at the 5 per cent confidence limits by probit analysis was $0{\cdot}106+0{\cdot}006$ mm.^{3}/kgm. (intraperitoneal). The corresponding *LD*50 for the hibernating group was $0{\cdot}072 \pm 0{\cdot}012$ mm.^{3}/kgm. intraperitoneal.

The increased susceptibility of the hibernating group to the anticholinesterase is possibly a reflexion of the increased stress placed upon the animal by the cold environment or the metabolic readjustment necessitated by coming out of hibernation.

Rate of Absorption of Supplementary Free Amino-Acids during Digestion

ANIMAL feeding studies have demonstrated that utilization of dietary protein is improved when an amino-acid deficiency is corrected by supplementation with free amino-acid. This greater utilization of protein is detected by the greater gain in body-weight of the test animal per unit of protein eaten, or by an increase in the percentage of ingested nitrogen retained by the animal. The improvement of the nutritive value of bread[1], rice[2] and maize[3] by supplementation with amino-acid has been demonstrated.

Although these investigations clearly point to nutritional improvement, supplementation of food proteins has been criticized on the grounds that the free amino-acids may be absorbed into the bloodstream before the amino-acids liberated by digestion of the protein. If this were so, the full value of the supplement would not be realized, since it has been demonstrated that efficient synthesis of tissue proteins occurs only when all the essential amino-acids are supplied simultaneously in the proper proportions[4].

The experiments reported here were designed to compare the rate of absorption of a free amino-acid supplement with that of the amino-acids liberated by digestion of protein. Healthy mongrel dogs were fasted for an 18-hr. period before being fed a meal containing the test protein. Approximately 25 ml. of blood was obtained by cardiac puncture of the unanæsthetized dog immediately before the meal (zero time) and 1, 2, 3, 4 and 5 hr. after the meal. (The feeding tests and the blood sampling were carried out at the Food and Drug Research Laboratories, Inc., under the direction of Dr. M. Brin.) The plasma was analysed for the essential amino-acids by ion-exchange chromatography[5], except for tryptophan, which was determined by microbiological assay employing *Lactobacillus plantarum*.

The concentrations in the plasma of several essential amino-acids after the ingestion of a wheat gluten diet for dog No. 364 (with and without a lysine supplement) are compared in Fig. 1. After the unsupplemented wheat gluten meal, the first limiting amino-acid, lysine, shows a marked decrease. Typical non-limiting amino-acids, such as threonine and tryptophan, show a gradual increase and then a decrease during the five hours after the meal. The decrease in concentration of lysine indicates that some of the lysine reserve of the plasma is used up to allow partial utilization of the other essential amino-acids from the wheat gluten. This finding may explain why the determinations of biological value for low-quality proteins sometimes give higher values than would be expected from their amino-acid composition[6]. Apparently, the plasma can serve as an amino-acid reservoir and supply a limited amount of an amino-acid which is deficient in the protein ingested. Further amounts of limiting amino-acids may also be mobilized by depletion of the stores of labile protein. Therefore, in short-term studies a greater utilization of the dietary protein for tissue synthesis will be obtained than would be possible if the only amino-acid source were the food protein itself.

When wheat gluten supplemented with lysine is fed (2 gm. L-lysine monohydrochloride per 100 gm. protein, which is the optimum supplementation-level for bread determined by animal-feeding studies; ref. 1), the concentration pattern of the plasma lysine after the meal is similar to the pattern exhibited by the non-limiting essential amino-acids (see Fig. 1). Only threonine and tryptophan are shown in Fig. 1, but all the non-limiting essential amino-acids gave similar patterns. These results indicate a similar rate of absorption for the 'free' lysine and the amino-acids from the wheat gluten. This is evident because the increase in the concentration of plasma lysine would not extend over the first two hours after the meal nor would the lysine concentration be maintained as well after five hours if the 'free' lysine were absorbed at a markedly faster rate than the amino-acids from the protein.

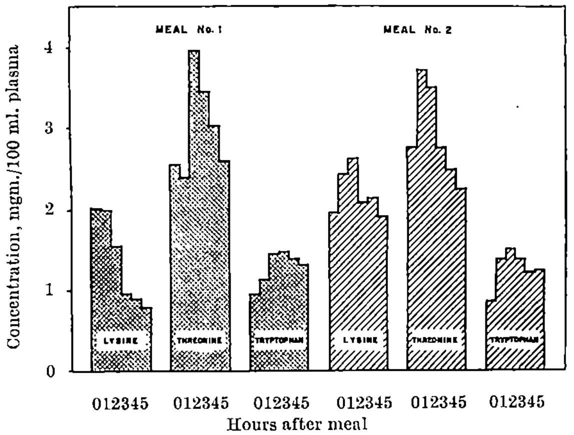

Fig. 1. Changes in blood plasma amino-acid after the ingestion of wheat gluten with and without L-lysine. Meal No. 1 contained 84·9 gm. wheat gluten (13·23 per cent nitrogen), 95·1 gm. sucrose, 20 gm. cottonseed oil and approximately 150 gm. water. Meal No. 2 contained 84·9 gm. wheat gluten, 1·3 gm. L-lysine-monohydrochloride, 93·8 gm. sucrose, 20 gm. cottonseed oil and approximately 150 gm. water

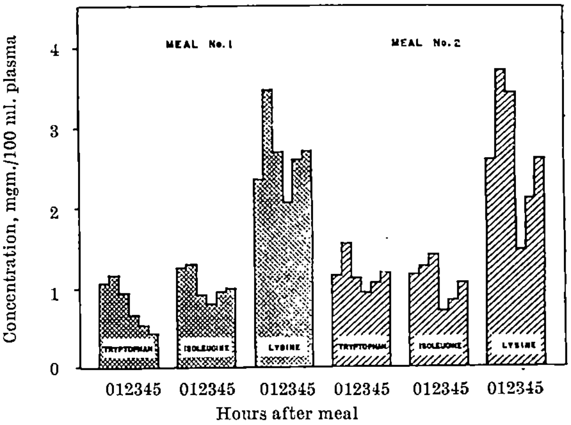

Fig. 2. Changes in blood plasma amino-acid after the ingestion of gelatin with and without L-tryptophan. Meal No. 1 contained 70·5 gm. gelatin (14·52 per cent nitrogen), 109·5 gm. sucrose, 20 gm. cottonseed oil and approximately 150 gm. water. Meal No. 2 contained 70·5 gm. gelatin, 0·3 gm. L-tryptophan, 109·2 gm. sucrose, 20 gm. cottonseed oil and approximately 150 gm. water

An identical experiment was carried out on gelatin with and without supplementation with tryptophan using dog No. 365. The results are presented in Fig. 2. The tryptophan deficiency is revealed by a decided lowering of the concentration of plasma tryptophan after a gelatin meal. When this deficiency is corrected by addition of free tryptophan to the gelatin (0·5 gm. L-tryptophan per 100 gm. protein), the plasma tryptophan pattern after the meal is similar to the patterns of the other non-limiting essential amino-acids. This indicates that the free tryptophan is absorbed into the blood at a rate similar to that of the amino-acids from the gelatin.

Thus direct studies *in vivo* indicate that the addition of a free amino-acid to a protein is a practical method of overcoming an amino-acid deficiency of the protein. Since the amino-acid deficiency in the blood is corrected at the time when the other essential amino-acids are present at their maximum concentrations, optimum utilization of the essential amino-acids from the protein should be realized.

Significance of Urinary Vanillic Acid

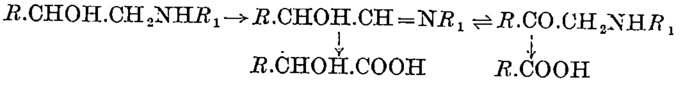
As a result of the observation that vanillic acid was excreted in abnormal quantities by some subjects exposed to stress, Smith and Bennett[1] suggested that the substance might be a metabolite of adrenaline or noradrenaline. In a recent communication[2] Shaw and Trevarthen considered these conclusions to be unjustified, since natural dietary precursors of the acid exist ; in particular these authors found increased excretion of vanillic acid by one subject following ingestion of coffee. We therefore wish to emphasize that we were well aware of these facts long before we even observed high values in stress and carefully considered them before allowing our conclusions to appear in print ; in point of fact I postulated that vanillic acid might be an adrenaline metabolite so long ago as 1954, but was for some time unable to obtain sufficiently unambiguous confirmatory evidence, since the technical imperfections of chromatographic methods coupled with the variations in excretion-rate observed in normal subjects were sufficient to mask any changes that may have occurred using other conditions of stress. A further experiment, which did not in fact confirm a high excretion of vanillic acid in driving-stress, has been the subject of a recent communication[3].

However, other observations, mostly of a rather scattered nature, have served only to convince us that the substance may arise endogenously, and an origin from adrenaline or noradrenaline is the only explanation we are able to offer. It must be admitted, though, that direct and conclusive evidence has not been easy to obtain. Thus in an experiment in which adrenaline was infused intravenously into a subject, vanillic acid was conspicuous in being one of the very few urinary phenols which was *not* excreted at an enormously increased rate, possibly as the result of diuresis. Since in any event the metabolism of, say, intravenously infused adrenaline may by no means be identical with the metabolism of adrenaline released from the adrenals, we have preferred to base our conclusions on inferences deduced from studies of excretion despite the pitfalls that may arise because of the practical impossibility of controlling diet.

It is indeed true that much—probably most—of the vanillic acid in normal urine is of exogenous origin. This is only to be expected since the normal rates of secretion of the sympathomimetic amines cannot be very high. However, in our British subjects most of whom rarely drink coffee, the rate of excretion of vanillic acid is rather low. On the few occasions when quantities approaching those observed in stress have been noted in normal subjects, other metabolites of caffeic and chlorogenic acids have been equally evident ; these acids are probably quantitatively by far the most important exogenous source of vanillic acid. Studies on the metabolism of caffeic and its related acids have been carried out intermittently in these laboratories over a period of some five years ; even so, we have not as yet been able to reach definite conclusions. Differences between the observations of Shaw and Trevarthen[2] and of Booth *et al.*[4], and between both these groups and ourselves concerning the metabolites detected after administration of coffee, for example, seem to be too significant to be readily explained away by possible variations in the source of the coffee. Some degree of clarification has been achieved since we now believe that methylation of 3 : 4-dihydroxyphenyl groups on the 4- as well as on the 3-position occurs far more generally than has been previously indicated[1,4], and some previously published observations may require modification. For example, if our experience is any guide, the increased excretion of vanillic acid after coffee noted by Shaw and Trevarthen[2] may be perhaps somewhat exaggerated since using the chromatographic technique employed by these authors we would expect to observe not vanillic acid alone, but a composite spot consisting of vanillic, *iso*vanillic and *iso*ferulic acids, in varying proportions according to the subject.

The dietary origin of much of the aromatic material in urine has been confirmed in these laboratories. Four urine samples were collected during the morning from each of seven subjects who had had no breakfast. As anticipated, the rates of excretion of many substances progressively diminished during the course of the experiments. In two subjects, however, well-defined increases in vanillic acid were observed in the acid-hydrolysed urines. In each case corresponding chromatograms of the unhydrolysed urines showed a parallel increase in 4-hydroxy-3-methoxymandelic acid. Since the latter compound is known to be a metabolite of noradrenaline[5,6], the experiments therefore indicate not only that vanillic acid may be formed endogenously but also support the suggestion of Smith and Bennett[1] that it is a metabolite of adrenaline or noradrenaline.

While there can be no doubt that the high values reported for vanillic acid were well beyond the normal range, the interpretation that the acid is a metabolite of adrenaline or noradrenaline is much less certain. In the first place, equally well-defined changes in the excretion of 3-ethoxy-4-hydroxybenzoic acid have now been reported in stress[3]. In view of the close chemical relationship of this substance to vanillic acid it would surely be too much of a coincidence if the increased excretion of both compounds had not a common basis. Until the possibility of biological ethylation has been clearly demonstrated the suspicion must therefore arise that both acids might have arisen because of the ingestion of sweets or other foodstuffs flavoured in some cases with vanillin, in others with ethyl vanillin. However, every care was taken to check that this was not so ; in the case of the two subjects discussed previously[3] the possibility can certainly be excluded. In the second place, the formation of vanillic acid from the phenylethanolamines requires a plausible, if hypothetical, metabolic pathway. Consideration of the likely properties of possible intermediates has led us to favour a scheme represented in its simplest form by :



$$\begin{array}{ccccc} R.\mathrm{CHOH.CH_2NH}R_1 & \rightarrow & R.\mathrm{CHOH.CH{=}N}R_1 & \rightleftharpoons & R.\mathrm{CO.CH_2NH}R_1 \\ & & \downarrow & & \downarrow \\ & & R.\mathrm{CHOH.COOH} & & R.\mathrm{COOH} \end{array}$$

It is therefore of interest that in a preliminary experiment, oral administration of adrenalone (3 : 4-$(\mathrm{OH})_2$ $\mathrm{C_6H_3.CO.CH_2NHCH_3}$) to a human subject has been found to result in the excretion of grossly abnormal quantities of vanillic, *iso*vanillic and 4-hydroxy-3-methoxymandelic acids. In the guinea pig, injection of either adrenaline or adrenalone has been reported to yield the same metabolite, believed to be protocatechuic aldehyde[7].

I wish to thank Mrs. G. A. Hill and Mr. J. Ratcliffe for experimental assistance.

Local Reaction to Non-metastasizing and Metastasizing Transplantable Tumours

The mechanism by which tumours spread into the surrounding tissues or produce metastases in distant organs is still an obscure problem. The reaction of the tissues of the host in relation to the rate of growth and metastasization has not been sufficiently investigated.

Bottiglioni and Prodi[1] observed that only the stroma of metastasizing tumours is rich in a metachromatic substance.

The present investigation aimed at studying the local reaction to non-metastasizing and metastasizing transplantable tumours, namely, the Walker adenocarcinoma and a rat sarcoma (non-metastasizing tumours at expansive growth), rat tumour Guérin *T*58 (non-metastasizing, in our strain, at infiltrative growth), rat tumour Guérin *T*8 (metastasizing, lymphotrope) and the rabbit Brown Pearce tumour (which produces metastases in lymph nodes and parenchymatous organs).

The tumours were transplanted with the usual technique, those of the rat subcutaneously, and the Brown Pearce tumour in the testis. The animals were killed when tumours had attained maximal development. Both primary tumours and metastases, when present, were removed with their surrounding tissue and studied with appropriative connective tissue stainings.

Investigations were carried out on material from sixty-five animals.

Around the grafts of Walker adenocarcinoma and rat sarcoma no connective tissue reaction was macroscopically detected; microscopically, the boundaries between tumour cells and host tissue are well outlined. The host tissue shows a considerable number of mast-cells, forming a sort of barrier around the tumour mass. Some of these cells are degranulated, some packed with granules. The fibroblastic reaction is rare.

Tumour *T*58 seems to become identified with the adjacent tissues. Its cells penetrate into the dermis and muscle, directly replacing the tissues without any kind of reaction.

Around tumour *T*8, in both the primary site and particularly around the metastases in superficial lymph nodes, a layer of loose connective tissue, sometimes of a mucous type, is observed; this tissue is rich in fibroblasts, and the loose fibrillar texture assumes a clear-cut metachromatic colour when stained with toluidine blue. Here and there the tissue takes the aspect of a thin extracellular network which shows intense metachromasia. If sections are pretreated with hyaluronidase, metachromasia does not occur. The mast-cells are scanty. Many round-shaped structures, which apparently are hectasic lymphatic vessels, are observed. The connective tissue is infiltrated with tumour cells which occasionally are also seen inside the lumen of these vessel-like structures.

Both around the primary tumour and the metastases (in the liver, kidney, lung, lymph nodes and peritoneal membranes) of Brown Pearce tumour an intense connective tissue reaction is observed with a large amount of highly metachromatic substance, which is destroyed by pretreatment with hyaluronidase. The tissue is of a loose fibrillar type, with often numerous fibroblasts and infiltrated with tumour cells.

The presence of a mast-cell barrier around the grafts of Walker adenocarcinoma and rat sarcoma which do not metastasize and grow extensively may indicate a defence against infiltration: such a hypothesis has already been suggested by Sylvén in relation to skin carcinogenesis[2]. This observation seems to be confirmed by the fact that there is little or no such reaction around tumour *T*58, which is infiltrative.

As regards metastasizing tumours, the tissue reaction is represented by a loose connective tissue which does not change into thickly fibrous tissue. This, with some differences, is a common character of the Brown Pearce and the *T*8 tumours. The reaction of connective tissue interposed between host and tumour tissue forms a sort of third section which is easily invaded by tumour cells and which, being rich in vascular formations (which are particularly evident around *T*8 tumour), facilitates their passage into the circulation and consequently the onset of metastases.

These considerations suggest that the rate of growth as well as the ability to induce metastases may not be directly dependent upon intrinsic characters of the cell but rather upon the reaction induced and established by the tumour cell in the host tissue.

Changes in the Potassium Concentration and Metabolism of Red Blood Cells of the Lamb

Many investigations have been made attempting to relate the potassium content and transport in red blood cells to the glycolytic activity of the cells[1,2]. Such investigations have utilized red blood cell suspensions which have been stored at low temperatures in order to obtain partial depletion of the cells with respect to potassium.

Widdas[3] has shown that the potassium content of fœtal sheep red blood cells is considerably higher than that found in the mature animals of the same breed. At birth the potassium concentration in the cells is high and decreases with increasing age of lamb. Thus successive samples of red blood cells from the same lambs can produce systems in which marked differences in the concentration gradient $(K^+)_i/(K^+)_o$ exist.

In preliminary experiments, we have made measurements of the potassium and sodium content, oxygen uptake and glycolytic activity of red cells obtained from lambs over the period 12–60 days of age.

Venous blood samples were taken into heparin, centrifuged, the red blood cells isolated, washed with

phosphate buffer solution (1·5 ml. $M/2$ potassium dihydrogen phosphate, 8·5 ml. $M/2$ disodium hydrogen phosphate, 240 ml. 0·9 per cent sodium chloride, glucose $M/100$) and resuspended in an equal volume of the same medium. After preliminary incubation to allow complete oxygenation, samples were taken for measurement of the initial potassium and sodium contents of the cells and lactic acid content of the medium. Replicate samples were then incubated (37° C.) for 2 hr. in a Warburg apparatus with air as the gas phase, when final estimations of potassium, sodium and lactic acid content were again made. Potassium and sodium were measured directly from centrifuged cells using a Beckman flame photometer; lactic acid contents of the media were measured by the method of Barker and Summerson[4].

The results are shown in Tables 1 and 2. Within the period 12–60 days of age, in each of the lambs used, large decreases in red cell potassium content were observed whereas the sodium content rose appreciably. Uptake of oxygen by the red cells decreased with increasing age of the lambs but no regular trend was observed with respect to lactic acid production by the same cell samples. Incubation in the presence of iodoacetate resulted in great reduction in the lactic acid production without change in the cell potassium content. In anaerobic conditions (oxygen-free nitrogen as gas phase and chromous chloride in centre wells of flasks), however, the red cells lost an average of 17 per cent of their potassium in 3 hr.

Table 2

Lamb No.	Age (days)	Incubation conditions	[Na⁺] (m.equiv./l.) Initial	[Na⁺] (m.equiv./l.) Final	[K⁺] (m.equiv./l.) Initial	[K⁺] (m.equiv./l.) Final	$Q_{\text{lactic acid}}$

4	12	3 hr. N_2 + 0·001 M IAA	74	86	53	41	0

Thus there appears to be little correlation between the potassium retention and glycolysis, but rather more between oxidative metabolism and maintenance of the potassium content of the cells.

Consideration of the changes observed in intracellular potassium concentration with age compared with the concomitant changes in total metabolic activity indicates that while decreases in potassium concentration of the order of 90 per cent occurred, oxygen usage declined to about half, and glycolytic activity to a slightly less extent.

Thus it is suggested that red blood cell suspensions such as these, in which large changes in intracellular potassium and sodium concentrations occur naturally, may provide more suitable material for investigations attempting to relate potassium retention to other cellular characteristics. Particularly indicated are studies involving the use of radioactive potassium, which is not available in sufficient activity in Australia, to estimate the degree of dependence of potassium transport and concentration on the metabolic activity of lamb red blood cells.

Serum Lipoproteins and Blood Coagulation

INHABITANTS of the highlands of New Guinea eat very little fat in their diet, have low levels of serum cholesterol, and rarely suffer from coronary heart disease[1]. This is in accord with experiences in other primitive races, and contrasts sharply with what is found among Australians and others of European origin, thus providing indirect support for the lipid infiltration theory of atherogenesis. With the thrombogenic theory in mind it would be valuable to gather information about coagulability of blood in different races, and this, to a limited extent, has been done in Australia and New Guinea.

Observations show that blood clots faster in natives than in Australians. The average whole-blood clotting times measured in duplicate in siliconed glass tubes were 26·6 and 28·6 min., respectively ($P < 0·01$), and the Stypven times (recalcified platelet-poor plasma accelerated with Russell's viper venom) were 41·4 and 72·2 seconds ($P < 0·001$). There was no significant correlation between these two clotting tests, and neither bore any relation to the levels of serum cholesterol or phospholipids. However, further analysis suggested that Stypven times were markedly affected by the serum lipoproteins. This was the case in both the aborigenes and Australians (40 and 26 men respectively) and accounted in part for the overall difference between the two racial groups. The lipoprotein fractions were measured as milligrammes of cholesterol eluted from paper strips after electrophoresis[2]. The partial correlation coefficient for Stypven time and alpha-cholesterol was positive and highly significant: on the other hand, the coefficient for Stypven time and beta-cholesterol was negative but not significant. The regression relationships were as follows: Stypven time (sec.) $= 50{\cdot}51 + 0{\cdot}80\alpha - 0{\cdot}8\beta$ for the Australians, and $40{\cdot}32 + 0{\cdot}46\alpha - 0{\cdot}09\beta$ for the natives.

The results offer no direct support for a thrombogenic factor in coronary heart disease, but they do suggest that a constituent of alpha-lipoprotein delays clotting in the Stypven test. Whatever may be the nature of this inhibiting factor, there is evidence to suggest that it is not cholesterol itself[3]. In order to confirm these observations further study of the effects of the specific phospholipid and fatty acid constituents of alpha-lipoprotein on the Stypven system will be necessary.

Effect of Diphosphopyridine Nucleotide on the Inhibition of Rat Liver 3-Hydroxyanthranilic-Acid Oxidase by 2-Acetylaminofluorene and N-2-Fluorenyl-diacetamide

Dunning *et al.*[1] demonstrated that bladder cancer due to 2-acetylaminofluorene was produced in almost all rats (strain Fisher 344) on a diet containing large quantities (1·4–4·3 per cent) of tryptophan. On the other hand, rats on a diet containing smaller amounts of tryptophan did not develop bladder cancer. We showed that the administration of 2-acetylaminofluorene inhibits 3-hydroxyanthranilic-acid oxidase in rat hepatic tissue[2], with consequent accumulation of the two carcinogenic *o*-aminophenolic compounds 3-hydroxyanthranilic acid and 3-hydroxykynurenine[3]. It seemed of interest to pursue these studies in order to elucidate the mechanism of this inhibition.

Kielley[4] has demonstrated that several carcinogenic fluorene compounds inhibit glutamic dehydrogenase; N-2-fluorenyl-diacetamide would therefore act by blocking the utilization of diphosphopyridine nucleotide[5]. In view of this, it seems probable that 2-acetylaminofluorene inhibits 3-hydroxyanthranilic-acid oxidase by affecting the utilization of diphosphopyridine nucleotide (which seems to take part in the reaction[6]). In order to test this hypothesis, we performed new experiments with 2-acetylaminofluorene and N-2-fluoroenyldiacetamide.

Livers, from rats of unspecified strain weighing about 200 gm. and which had received 0·1–0·2 per cent of Hoffmann–La Roche 2-acetylaminofluorene in their diet (Coward) for 2–6 days, were used. The liver was excised, immediately homogenized in the cold in a Potter blendor with Krebs–Ringer phosphate (3 ml. per gm. of tissue), and centrifuged. The supernatant was used as enzyme source.

The incubation mixtures had the following composition: 1 ml. of supernatant; 3,000 μgm. 3-hydroxyanthranilic acid (Hoffmann–La Roche) diphosphopyridine nucleotide (I.S.I.) at a final concentration of 2×10^{-5} *M* (made up to final volume of 6·34 ml. with Ringer's solution). At the same time mixtures without diphosphopyridine nucleotide, without 3-hydroxyanthranilic acid and without tissue were prepared. The mixtures were incubated at 37° C. for 90 min. with frequent shaking.

Quinolinic acid was determined according to the method of Rabinovitz *et al.* with slight modifications[7].

Livers of rats of the same strain, weight and age, which had received the same diet, but without 2-acetylaminofluorene, were assayed for their ability to convert 3-hydroxyanthranilic acid into quinolinic acid under identical experimental conditions.

In one experiment 546 μgm. of quinolinic acid was formed in the presence of normal rat liver (diphosphopyridine nucleotide does not affect this enzymatic activity); 273 μgm. quinolinic acid was formed in the presence of liver from a rat treated with 2-acetylaminofluorene (diphosphopyridine nucleotide added to these incubation mixtures brings the enzymatic activity almost back to normal).

In other experiments we studied the 3-hydroxyanthranilic-acid oxidase activity in rats treated with parenteral injections of N-2-fluorenyl-diacetamide (for which we thank Prof. Kielley and Prof. Weisberger) and the effect of diphosphopyridine nucleotide on this activity *in vitro*. Rats weighing about 200 gm. were treated for four days parenterally with N-2-fluorenyl-diacetamide (40 mgm. in 2 ml. of sterile olive oil per day); on the fifth day the treated animals and the controls, which received 2 ml. of olive oil per day for four days, were killed by decapitation and the 3-hydroxyanthranilic-acid oxidase in the liver determined as described above.

In one experiment 525 μgm. of quinolinic acid was formed in the presence of normal rat liver (diphosphopyridine nucleotide does not potentiate this enzymatic activity); 315 μgm. of quinolinic acid was formed in the presence of liver from a rat treated with N-2-fluorenyldiacetamide (diphosphopyridine nucleotide added to these incubation mixtures brings the enzymatic activity back to normal).

Thus, *in vitro*, diphosphopyridine nucleotide abolished the inhibition of rat liver 3-hydroxyanthranilic-acid oxidase produced by 2-acetylaminofluorene and N-2-fluorenyldiacetamide.

Our work therefore confirms Kielley's[4,5] on the inhibitory influence of fluorene carcinogens on the utilization of the pyridine coenzymes. Moreover, these investigations lead to the following important suggestion: the inhibition of 3-hydroxyanthranilic-acid oxidase is observed both in hepatic tissue of rats bearing Oberling, Guérin and Guérin myeloma at the leukæmic phase[8] and in the hepatic tissue of rats treated with 2-acetylaminofluorene and N-2-fluorenyldiacetamide. In both cases this inhibition is abolished by diphosphopyridine nucleotide.

A Bucco-hypophysial Canal in *Elops saurus*

A PERSISTENT Rathke's pouch in the form of a hollow bucco-hypophysial canal piercing the parasphenoid bone has been reported in young animals and adults of the two recent brachiopterygian genera *Calamoichthys*[1] and *Polypterus*[2,3]. The recent coelacanthid *Latimeria* is reported to possess a partly hollow cord of glandular tissue running from the adenohypophysis towards the roof of the mouth cavity[4]. Besides, there is a canal in the parasphenoid, but this canal, which is regarded as a vestige of Rathke's pouch, does not reach the fossa hypophyseos[5]. In the early fossil coelanthids the fossa hypophyseos is in communication with the mouth cavity by means of a canal piercing the parasphenoid and the same is true of the Devonian rhipidistid crossopterygians[6]. In the fossil actinopterygians this communication is rarely retained and has been observed in a few instances only[7-9]. In the recent actinopterygians it has been hithorto unknown.

It was very surprising, therefore, to find a wide canal connecting the pituitary and the oral epithelium in young individuals of the primitive teleost *Elops saurus* (Fig. 1). No doubt this canal, which strongly resembles that of *Polypterus*, represents a rudiment of the original pharyngeal pouch.

The canal originates at the anterior end of the adenohypophysis from several follicle-like pockets, which contain tall cells, apparently with glandular properties. In its proximal part, the canal is directed straight ventralwards until it reaches the parasphenoid. There the lumen becomes narrower and the canal turns at right angles rostrally and slightly ventrally, before passing obliquely through the parasphenoid. Underneath this bone the canal opens into the pharynx as an elongated but rather narrow cleft.

The bucco-hypophysial canal is lined by a single-layered squamous epithelium, which nowhere carries cilia, in contrast to the condition in *Polypterus*, where a strongly ciliated region is found around the opening into the pharynx. The whole apparatus strongly suggests a mechanism for external secretion ; but no trace of secretion could be seen in the canal lumen of the specimens investigated.

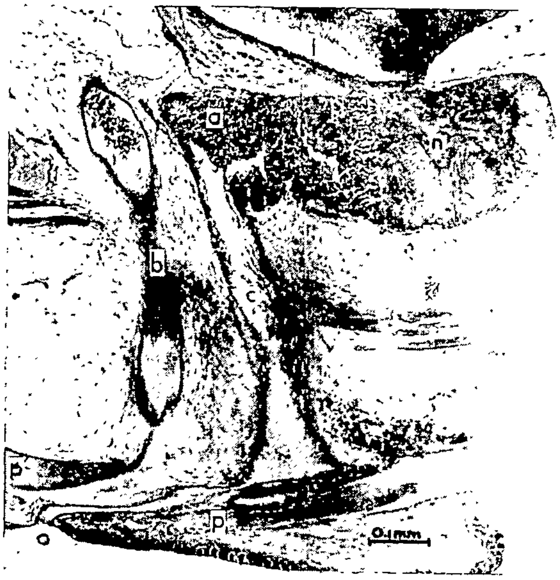

Fig. 1. *Elops saurus*, 60 mm. median section through the pituitary region showing : *a*, adenohypophysis ; *b*, blood vessel ; *c*, bucco-hypophysial canal ; *i*, infundibulum ; *n*, neurohypophysis ; *o*, canal opening into the pharynx ; *p*, parasphenoid

There can be scarcely any doubt that the existence of a persistent communication between the pituitary and the roof of the pharynx is an archaic feature, which may possibly even recall the condition in the ascidians[10]. Anyhow, this observation further strengthens the opinion[11] that the members of the family Elopidae are the most archaic of the recent teleosts. At the same time it recalls the recent suggestion[12] that the elopids are holosteans rather than teleosts.

Soluble Nucleotides and Nucleotide–Amino-Acid Compounds of Yeast

AN investigation of the soluble nucleotides in food yeast (*Torulopsis utilis*) has shown that a complex metabolic pool of these compounds is maintained in growing cells. Marked changes in the size and composition of this pool under different physiological conditions indicate that the metabolism of nucleotides is closely related to the biosynthesis of nucleic acids and proteins. Some evidence has been obtained that, in exponentially growing cells, certain of the nucleotides occur in combination with amino-acids or simple peptides.

Soluble nucleotides were extracted from yeast by means of ice-cold 60 per cent ethyl alcohol. After removal of the solvent by evaporation *in vacuo*, and filtration to free the extract from lipid material, the nucleotides were separated by column chromatography on the basic exchange resin 'Dowex-1' (× 10). The general method of preparation and operation of the column followed that of Brumm, Potter and Siekevitz[1], except that the elution gradient was steepened by reducing the mixing volume in two stages. In this way, improved separation and sharper peaks were obtained in the later stages of elution. A typical example of the separations achieved by this method is shown in Fig. 1. Identification of the nucleotide peaks is based on co-chromatography with pure compounds, where available, and on measurements of ultra-violet absorption spectra under acid and alkaline conditions.

The elution pattern shown has been consistently observed when cells, in the exponential phase of growth, were rapidly separated from the culture medium by filtration and immediately treated with ice-cold absolute alcohol. Prompt harvesting and fixation are important, since otherwise marked changes occur in the nucleotide pool. For example,

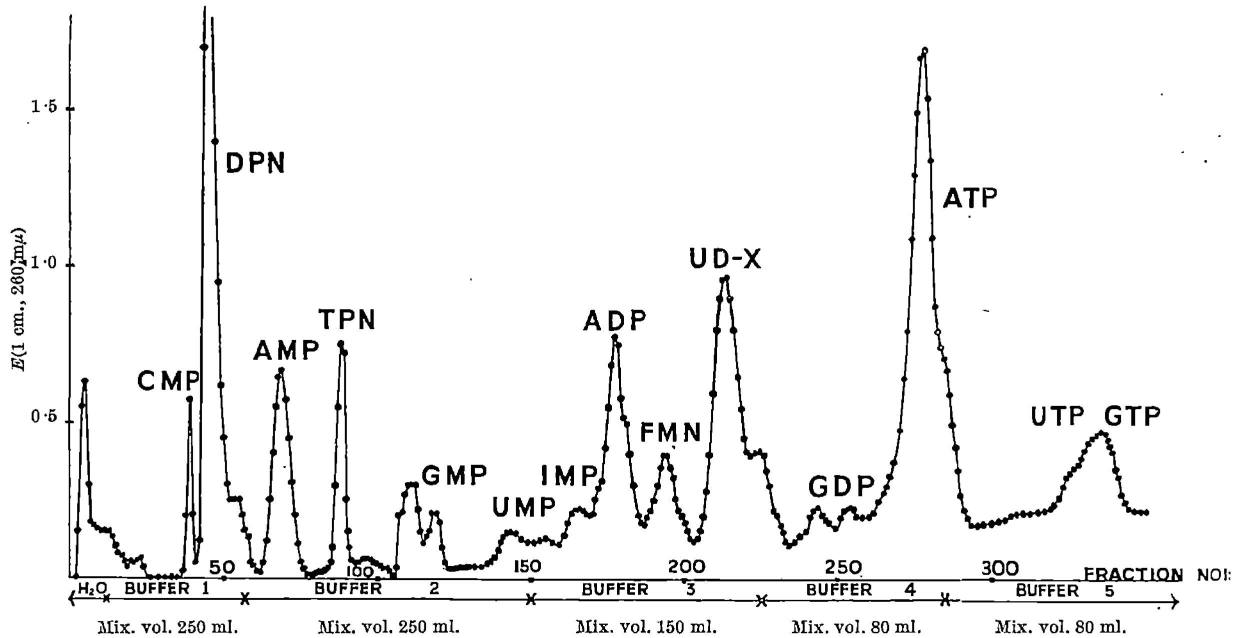

Fig. 1. Soluble nucleotides of *Torulopsis utilis*. Extract from 1·56 gm. fresh yeast eluted from 'Dowex-1' (formate) 200–400 (×10); column 16 × 1·5 cm.; fractions 3·7 ml. Buffers: (No. 1), 1 *N* formic acid; (2), 4 *N* formic acid; (3), 4 *N* formic acid – 0·2 *M* ammonium formate; (4), 4 *N* formic acid – 0·4 *M* ammonium formate; (5), 4 *N* formic acid – 0·8 *M* ammonium formate.

AMP, ADP, ATP, adenosine 5′ mono-, di- and tri-phosphates; UMP, UDP, UTP, uridine 5′ mono-, di- and tri-phosphates; GMP, GDP, GTP, guanosine 5′ mono-, di- and tri-phosphates; CMP, cytidine 5′ monophosphate; IMP, inosine 5′ monophosphate; DPN, TPN, di- and tri-phosphopyridine nucleotides; FMN, flavin mononucleotide

cells harvested less rapidly by centrifugation contain much larger quantities of the monophosphates inosine 5′ monophosphate and uridine 5′ monophosphate.

The composite peak, uridine 5′ diphosphate-*X*, has only been found in extracts prepared from exponentially growing cells; it undergoes a sharp decline if the culture is harvested by centrifugation. Examination of the peak has shown that on hydrolysis with 1 *N* acid it yields four amino-acids, which have been identified by column and paper chromatography as aspartic acid, glutamic acid, arginine and alanine. It has not been possible to separate the nucleotide and amino-acid components by purification on the acidic resin, 'Zeokarb 225', on charcoal, or by paper electrophoresis.

A more thorough investigation of the uridine 5′ diphosphate-*X* peak is now in progress, and an attempt is being made to estimate the rate of turnover of the constituent amino-acids by means of substrates labelled with carbon-14. Thus more decisive evidence may be gained of the significance of these constituents in the synthesis of peptides and proteins in yeast and of their relation to similar nucleotide compounds which have been detected in other micro-organisms[2-5].

Root Nodules in *Discaria toumatou* Raoul Choix

Discaria toumatou is a thorny shrub belonging to the Rhamnaceae. It is endemic in New Zealand and is common in mountain valleys on the eastern side of the Southern Alps. The root systems of plants growing in a number of widely separated localities in the South Island have been examined and all have been found to be nodulated.

Fig. 1 shows the nodules which by continuous dichotomous branching give rise to coralloid clusters. Morphologically they have a number of features in common with previously described non-leguminous nodules[1]. They represent modified roots, in which there is no distinct apical meristem and with many of the cortical cells enlarged and occupied by an endophyte. In infected cells immediately below the apex the endophyte appears to be filamentous. Sections cut farther down show that the endophyte produces bunches of vesicles approximately 4μ in diameter. In fresh preparations mounted in water, these bunches can be freed from the host cells by squashing and some of the vesicles become detached together with a short length of hypha-like connecting strand. Nuclei in infected cells are large and misshapen. In the basal regions of the nodule branches there is a zone in which the contents of the infected cells are more amorphous and appear to be undergoing degeneration.

The taxonomic position of *Discaria* in relation to other genera with root nodules is of interest. In the Rhamnaceae, there is another genus, *Ceanothus*, known to have nodules. All three genera of the Eleagnaceae have been found nodulated and Hutchinson[2] places this family together with the Rhamnaceae in a common order, the Rhamnales. This group, then,

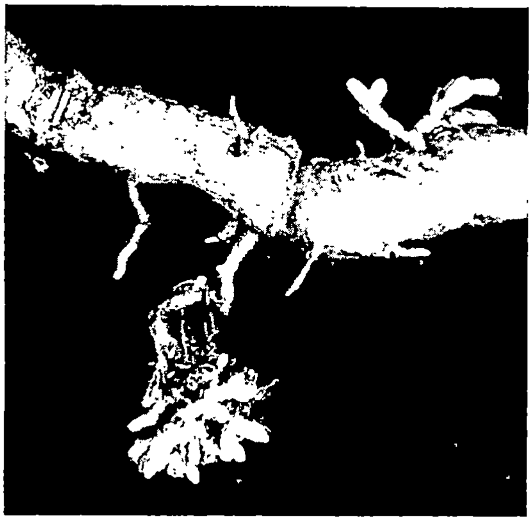

Fig. 1. Nodules on *Discaria toumatou*. (Actual size)

contains five of the nine non-leguminous dicotyledonous genera which have been reported to bear nodules of the general type described here.

Application of Autoradiographic Techniques to Studies of Shoot Apices

In contrast to the earlier widely accepted concepts of the structure and growth of the shoot apex, Buvat and his associates[1–3] have proposed an alternative interpretation. According to this newer view the most apical, axial cells of shoot apices in a variety of plants do not have histogenic or organogenic roles during vegetative growth. The criterion of activity was based on the frequency of mitosis. This information was obtained by counting mitotic figures in various zones of the shoot apex and then presenting this information in the form of a composite diagram. The results of these investigations have been challenged by Gifford[4] and by Popham[5]; the latter used essentially the same methods as did the French workers.

It would seem, then, that more definitive evidence is necessary before any final conclusions can be drawn. The existing results are limited largely by the techniques used. The simple counting of division figures as an indication of local frequencies of mitotic activity has several drawbacks, including possible periodicity, either local or general. Also, mitotic frequency diagrams are meaningful only if the cell size is relatively uniform in the areas which are being compared. However, this is not the case in shoot apices. Therefore, new techniques must be applied to a more thorough analysis of the problem.

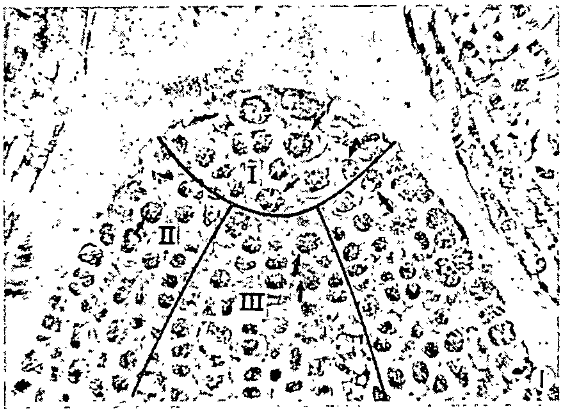
A suggestion of a new approach came from the recent work of Clowes[6] on the localization of nucleic acid synthesis in root meristems by using autoradiographic techniques.

In our present investigations we have applied the autoradiographic localization of nucleic acid synthesis to shoot apices, using phosphorus-32 in the form of inorganic phosphate as the labelling substance. Several plant species were exposed to concentrations of phosphorus-32 ranging from 10 to 50 μc./ml. by immersing either the cut terminal portions (approximately 6–8 in. long) or the roots of the intact plants in Hoagland's solution with phosphorus-32 added, for periods of 1–7 days. Shoot tips were then fixed in formalin–acetic alcohol, dehydrated, embedded in paraffin and sectioned at 8–10μ. Using high-resolution stripping film ('Kodak' Fine-Grain Autoradiographic Stripping Plate *AR*. 10), the technique as outlined by Taylor and McMaster[7] was employed. The prepared autoradiographs, in which the sections and the film are permanently superimposed and in register, were mounted in an oil with a refractive index approximating that of the unstained sections, thus minimizing the light scatter by the section while the autoradiographic image was photographed by dark-field illumination. Then, without changing the stage setting of the microscope, xylol was injected under the coverslip to lower the refractive index of the mounting medium, thus producing a more intense phase-contrast image to permit the photographing of the section.

In this preliminary report we shall confine our observations to just one of the species investigated—namely, *Pinus lambertiana*. Fig. 1 shows the phase-contrast image of a median longitudinal section of the shoot apex and Fig. 2 the corresponding autoradiograph. This shoot was exposed to phosphorus-32 solution for a period of three days, and the section was extracted according to the schedule of Taylor and McMaster, using finally a hydrolysis in *N* hydrochloric acid at 60° C. for 12 min. to remove the ribonucleic acid. After this treatment the major part of the radioactivity is due to the phosphorus-32 incorporated into newly synthesized deoxyribonucleic acid, with some possible activity in proteins.

Cytological zonation of the apex is evident in Fig. 1, namely, a terminal zone (I) consisting of large vacuolate cells with correspondingly large nuclei, a peripheral zone (II) of smaller cells and a central column of rib meristem (III). For convenience of presentation, zone I includes apical initials and central mother zone, an organization frequently recognized by others. According to the French workers the site of intense mitotic activity is in the upper portion of the peripheral zone, which they assume to be self-perpetuating, with little or no activity in the terminal zone. Although no division figures are evident in Fig. 1, there is evidence of synthesis of deoxyribonucleic acid, as shown in Fig. 2. Some of these centres of high radioactivity, as indicated by the dense clusters of silver grains, clearly fall within the terminal zone. These centres can be seen to coincide with nuclei in Fig. 1. There are certain highly refractive areas in the developing pith and in the leaves which over-arch the apex; these are not to be confused with light scatter due to exposed silver grains in the emulsion.

The presence of synthesis of deoxyribonucleic acid, as evidenced by the incorporation of radioactive label, can be taken to be indicative of subsequent mitotic activity, in the absence of metabolic turnover of deoxyribonucleic acid or the occurrence of endo-



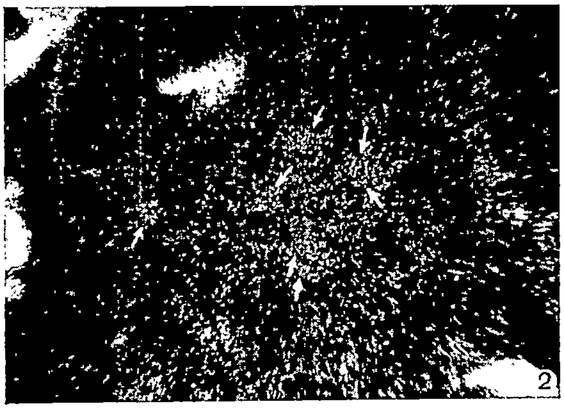


Fig. 1. Longitudinal section, shoot apex of *Pinus lambertiana* (phase-contrast image) showing cytological zonation, that is, zone I, terminal zone; zone II, peripheral zone; zone III, rib meristem. Arrows indicate nuclei which incorporated large amounts of phosphorus-32 into deoxyribonucleic acid

Fig. 2. Autoradiograph of same section (photographed with dark-field illumination). Centres of radioactivity, indicated by arrows, coincide with nuclei indicated in Fig. 1. Scattering of light, due to refractiveness of certain cells and/or damage to the photographic emulsion, is evident near the tip of the apex, in young leaves, and in developing pith cells, but does not represent radioactivity. (Both figures × 210)

mitotic reduplication. The very presence of these highly radioactive centres within the bounds of the terminal zone would indicate that these nuclei do divide since the alternative sequels to synthesis of deoxyribonucleic acid can very likely be ruled out. If the French workers were correct in their interpretation, the centres of high activity would be immediately below the line separating the terminal and peripheral zones, but not in the terminal zone.

Autoradiographs (not shown here) showing total nucleic acid synthesis (deoxyribonucleic acid plus ribonucleic acid) indicate a rather high level of activity which appears to have a relatively uniform distribution throughout the apex. However, it should be pointed out that owing to such complicating factors as 'background activity', which is more or less uniformly distributed in the emulsion, subtle differences of degree of activity as well as its total absence are difficult if not impossible to demonstrate by these means.

At the present stage of these investigations it would seem that the observations made here for *Pinus* would apply generally to the other species examined, which include *Glycine max*, *Chenopodium alba* and *Ginkgo biloba*. A more extensive report of these observations will be published later.

Induced Apospory in Polypodiaceous Ferns

The induction of outgrowths of gametophytic tissue from the sporophyte in mosses has been accomplished many times since Pringsheim[1] first reported it. In the ferns, the aposporous production of fully sexual gametophytes from genetically normal sporophytes has been considered to occur less readily. Although various forms of apospory in a number of ferns have been reported by Goebel[2] and others, the only well-investigated example of its induction and consequences is in *Osmunda*, where apospory was induced by continued maltreatment and malnutrition of the sporeling[3].

Recent experiments have shown that apospory can be regularly induced in normal sporelings in at least two other species of fern, namely, *Thelypteris palustris* and *Pteridium aquilinum*. Sporelings were raised from gametophytes grown in pure culture from spores from wild populations of these ferns. The first or second leaves of the sporelings were detached when fully expanded and placed on sterile mineral – agar slopes, a small square of glass being used to press a portion of each lamina close to the medium. With only one exception (where the leaf died) in numerous experiments, filaments have grown out from the margin or surface of the leaf (Fig. 1). The filaments eventually gave rise to cordate gametophytes. In *Thelypteris* it was afterwards found that leaves up to at least the tenth continued to show this phenomenon.

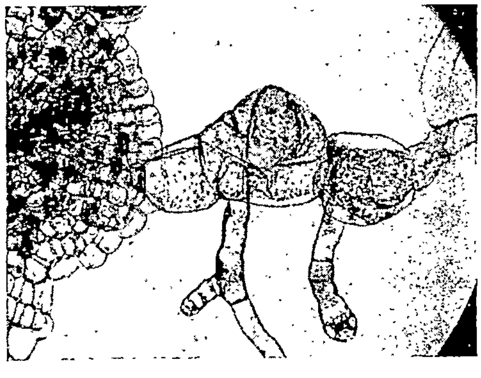

Fig. 1. *Pteridium aquilinum*. Filament growing out from marginal cell of the first leaf of a normal sporeling detached and placed on agar. (× 150)

It was considered possible that sporelings giving rise so readily to gametophytic tissue were abnormal, but no evidence could be found in support of this view. The sporelings arose after controlled fertilization and had every appearance of being produced by the normal sexual means. Furthermore, the development of the sporelings after the removal of the leaves for experimentation showed no peculiarities.

Additional evidence in favour of the normality of the intermediate sporelings was obtained by comparing the amount of deoxyribonucleic acid in the nuclei of the gametophytes produced aposporously with that in the nuclei of the original. Specimens of both sets of gametophytes were fixed, sectioned, and the sections stained simultaneously in Feulgen's reagent according to Partanen's schedule[4]. The intensity of the staining was measured with a scanning microspectrophotometer built by Deeley[5]. The results are shown in Fig. 2. As expected, the amounts of deoxyribonucleic acid in the nuclei of the two sets of gametophytes are in the ratio 2 : 1. Some estimates were also made of the deoxyribonucleic acid in the nuclei of a young crozier from one of the sporelings. Because of the harder cell walls, few nuclei in these sections could be satisfactorily flattened for scanning, but the results obtained fully support the normality of the sporeling.

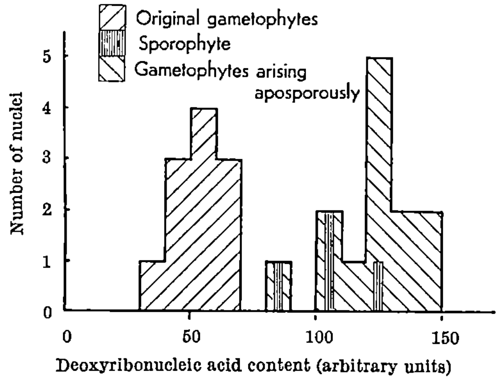

Fig. 2. *Thelypteris palustris.* Amounts of deoxyribonucleic acid in nuclei of normal gametophytes, a normal sporeling and gametophytes arising aposporously

It can be concluded, therefore, that by the technique reported here, outgrowths of gametophytic tissue can be obtained readily from the sporophytes of two species of polypodiaceous ferns without the intervention of meiosis. Gametophytes obtained in this way have produced sex organs, and sporelings raised from them are the subject of further study. There seems no reason why the technique should not be generally applicable in the ferns.

Symptoms of Calcium and Phosphorus Deficiency in Oil Palm Seedlings

Previous attempts[1,2] to induce symptoms of calcium and phosphorus deficiency in oil palm seedlings grown in water-washed quartz sand have failed. Symptoms have now been induced by growing oil palm seedlings in quartz sand purified by treatment with hot 1 per cent sodium carbonate and hot, constant-boiling hydrochloric acid.

The experimental methods used were based on those recommended by Hewitt[3] for critical work on nutrient deficiencies. Quartz sand obtained from a local riverine deposit was substantially freed from clay and organic matter by digestion in a Kestner apparatus[3] for two successive 4-hr. periods followed by a third digestion for 3 hr. with hot, constant-boiling hydrochloric acid. Free acid was removed by leaching with de ionized water derived from mixed-bed ion-exchange columns. The specific conductivity of this water was $0{\cdot}3 \times 10^{-6}$ mho cm.$^{-1}$ at 27° C. Adsorbed hydrogen ions were displaced by leaching with $0{\cdot}02$ M magnesium nitrate until the pH of the effluent exceeded 5·5. In calcium- and phosphorus-deficient nutrient solutions, sodium was substituted for calcium and sulphate for phosphate respectively. Iron was supplied as iron-ethylenediamine tetraacetic acid at a concentration equivalent to 5 p.p.m. ferric iron. In all other respects the nutrient solutions employed were identical with those used at Long Ashton[3]. Seedlings which had been grown in soil for the first two months from germination were transplanted to pure sand in bitumen-lined glazed porcelain pots in late April, and symptoms first appeared during early August.

Phosphorus Deficiency. The first symptom of this disorder was a general reduction in growth and vigour as compared with the complete nutrient control treatment. The oldest leaves became dull and assumed a pale olive-green colour (Munsell Color Fan 2·5*GY* 5/5). As the severity of the deficiency increased emerging leaves became progressively more chlorotic (Munsell 2·5*GY* 6/8) and terminal necrosis appeared on the oldest leaves. Necrotic areas were in general dark brown but their colour was somewhat variable. Where the necrosis developed rapidly, affected tissues were light brown (Munsell 5*YR* 4/5–3/3), but more usually the necrotic areas became blackish-brown or purplish-brown in colour. No

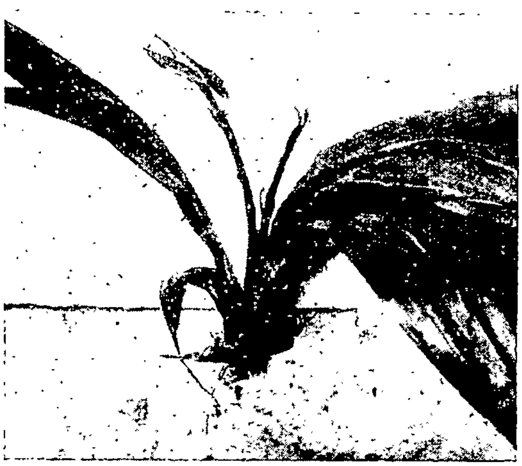

Fig. 1. A seedling deficient in calcium. The central leaves are malformed

obvious chlorotic band separated necrotic from healthy tissues when affected leaves were examined in reflected light. Examination in transmitted light revealed a pale band of tissue, with a water-soaked appearance, at the proximal limit of necrosis. This band was narrow, being about 2–3 mm. wide and yellow in colour (Munsell 10*Y* 6/7). These symptoms suggest that in phosphorus-deficient leaves collapse of cells occurs rather abruptly. Interveinal ochre spots (Munsell 7·5*Y* 6/7) were occasionally present near leaf margins but their significance is obscure. In phosphorus-deficient seedlings leaves are reduced in size and the plastochrone is increased.

Calcium Deficiency. The first characteristic symptom of this disorder was the appearance of a leaf which was abnormally short, narrow and rigid with prominent veins (Fig. 1). In slightly older leaves, which are normally bipinnate in form, one-half of the leaf blade was often narrower than the other with apical splitting and some terminal necrosis. As the deficiency became more severe, there was a progressive reduction in the area of emerging leaves ; this reduction exceeded 90 per cent in the leaves most malformed. Terminal necrosis became more severe and ultimately the leaves produced comprised merely the basal part of the petiole. Intermediate leaf shapes occurred in which the leaf blade was truncated and spatulate or strap-shaped with a slight apical indentation. No chlorosis was observed in association with the morphological changes described. Abnormal leaves were dark green (Munsell 5*GY* 4/3) and identical in colour with leaves of control plants receiving a complete nutrient solution.

These observations were made on a large experiment investigating macronutrient deficiency symptoms in seedling oil palms, and the results of this experiment will be published in greater detail elsewhere.

A Revised Interpretation of the Causes of Loss of Crops of Cotton in the Drier Regions of Uganda

For many years *Lygus vosseleri* Popp. has been considered to be the major cotton pest in Uganda[1].

Recent work at Serere in eastern Uganda suggests that this may not be true of the drier areas. Analysis of a large insecticidal experiment using DDT showed that a high degree of control of 'spiny bollworm' (*Earias* spp., Lepidoptera, Noctuidae) was being obtained, as illustrated by the results from a flower bollworm count (Table 1).

Table 1

Applications of DDT	Damaged flowers	
5	43	*L.S.D.*
3	109	at 5 per cent $P > 0{\cdot}01$
1	172	62·6
Control	204	

Subsequent analysis of sheds damaged by bollworm (which can be shown to be mainly due to *Earias* spp.) from this and many previous experiments showed that control of *Earias* by DDT has been achieved over many years but had escaped notice due to a preoccupation with efforts to correlate increases of yield with *Lygus*.

It has been impossible to correlate the assessment of any form of damage by *Lygus* with subsequent increases in yield, but highly significant correlations are obtained with all measures of bollworm infestation.

Laboratory work has shown that *Earias* larvæ are capable of doing very severe damage to young cotton plants, removing many small fruiting points, 'tattering' leaves and boring into the growing points. In fact, at this stage of growth of the plants, *Earias* is not a true 'bollworm' but is a general feeder on fruiting points and growing points. The larvæ wander extensively over the plant and, at this stage, no single boll is large enough to sustain a larva through to maturity. It is suggested that this allows considerable pick-up of DDT, especially in the younger instars, resulting in the observed control. So far as can be ascertained, this would appear to be the first recorded case of economic control of *Earias* spp. with DDT on cotton.

The spraying practice now being advised for peasant cotton[2], originally directed against *Lygus* which is probably not responsible for the bulk of the damage, is giving adequate protection against *Earias*.

Chromosome Aberrations in Calcium-deficient *Tradescantia* produced by Irradiation

The lack of calcium in *Tradescantia* microspores and in barley seeds has been demonstrated to increase the frequency of X-ray-induced chromosome aberrations above similarly irradiated material grown with optimal calcium[1,2]. Mechanisms by which the lack of calcium could cause such an effect have been discussed[1]. It is necessary to distinguish between two important alternatives : (1) does the absence of calcium confer a unique instability on chromosomes as observed by increased breakage, or (2) is the mechanism of increasing breakage more indirect ? A likely possibility in the latter category could involve low or high viscosity of the nucleoplasm. Calcium, potassium, sodium, magnesium and manganese are reported to influence viscosity to various degrees[3]. If the increased chromosome sensitivity to radiation acts by a change in viscosity, then metals other than calcium should have similar effects. Previously, magnesium and manganese have been shown to have no effect on modifying the frequency of chromosome aberrations by X-rays[1]. Sodium is not usually an essential element in plants. Potassium is considered here in experiments with *Tradescantia*.

In an extensive series of experiments with various plant species Lundegårdh and others[4] have demonstrated a reciprocal relationship between potassium and calcium. As a rule in nutrient culture when potassium concentration is low and calcium is optimal, then more calcium accumulates in leaves and flowers than potassium as determined by flame photometry. High potassium in the nutrient solutions greatly reduces the movement and accumulation of calcium above the roots. In the latter instance potassium accumulates in the upper part of plants in high concentrations.

The methods have been described by which inflorescences of *Tradescantia paludosa* were cultured and irradiated[1]. As seen in Table 1, limiting potassium in water culture has little or no effect on the frequency of chromosome interchanges. At the lowest concentration of potassium (2·4 p.p.m.) interstitial deletions were significantly lower than controls. When calcium was limiting, both interchanges and interstitial deletions were 40 per cent higher than controls. Thus, calcium seems to be the key metal effecting radiosensitivity.

Nilan and Phillips[2] have recently reported experiments with barley seeds collected from plants grown on low calcium. Twice as many chromosome aberrations were produced in X-rayed seeds lacking calcium as in X-rayed seeds with optimal calcium. There were no differences in aberration frequency between the two levels of calcium when thermal neutrons were employed. These latter results are expected since proton and alpha tracks can break a chromosome whether it is labile or not. *Tradescantia* microspores at two levels of calcium were treated with sparsely ionizing gamma-rays. In Table 2 the differences between treatments are of the magnitude produced by 250 kVp. X-rays (Tables 1 and 3). Hard X-rays and gamma-rays have similar properties in respect to their ion densities[5]. A more labile chromosome would be expected to exhibit a higher sensitivity to these sparsely ionizing radiations.

Factors which modify radiosensitivity (for example, cysteine and cysteamine[6], carbon dioxide[7], carbon monoxide[8] and potassium cyanide[9]) are almost always dependent upon the presence of oxygen during irradiation. In the following experiment pre-purified nitrogen was used to X-ray inflorescences in absence of oxygen. A special 'Lucite' chamber was employed. Three evacuations and three nitrogen flushings were made before irradiation. From Table 3 we see that cells irradiated in nitrogen have about the same increase in sensitivity as cells treated in air. Apparently the influence of limiting calcium on chromosome breakability is independent of oxygen.

Table 1. A DOSE OF 400 R. OF 250 KVP. X-RAYS WAS GIVEN AT 100 R. PER MINUTE WITH 1 MM. ALUMINIUM AS FILTRATION

Table 3. THE 250 KVP. X-RAYS WERE GIVEN AT 5(NUTE
WITH 1 MM. COPPER AND 1 MM. ALUMINIUM A: ON

Treatment			Interchanges		Ir		Total cells
		p.p.m. Ca++	No.	Per cell		cell	
1,000 r.	Control	250	750	1·13		1·42	663
in	—Ca	6·2	467	1·16*		1·97†	402
nitrogen	—Ca	4·2	705	1·38		1·82†	511
400 r.	Control	250	417	0·64		0·64	652
in air	—Ca	6·2	231	0·71*		1·05†	324
	—Ca	4·2	261	0·71*	258	0·70*	369

* Not significantly different from control by χ^2 test, $P > 0·05$.
† Significantly different from controls, $P < 0·001$.

The results are compatible with the general hypothesis that chromosomes are inherently more sensitive to breakage at reduced levels of calcium. The increased radiosensitivity appears either in the presence or absence of oxygen. The evidence indicates that lowering the calcium concentration increases the sensitivity to radiation by raising the probability of a sparse track breaking a chromosome. Presumably fewer ionizations can cause a break.

This investigation was carried out under the auspices of the U.S. Atomic Energy Commission. The assistance of Mr. Fred Palace and Mrs. Lulu A. Grodzins is gratefully acknowledged.

Use of Artificially Liberated Larvæ in Experiments on the Setting Behaviour of *Spirorbis*

DURING a study of the systematics of the Spirorbinae (Serpulidae), it became clear that several forms are found characteristically on specific substrata. Whereas *Spirorbis borealis* Daudin occurs most abundantly on the brown alga *Fucus serratus*, *Spirorbis tridentatus* Levinsen (usually regarded as an ecophenotype of *Spirorbis borealis*[1]) is found only on stones and shells in dimly lit places. Another closely related form, which appears to be a distinct species previously confused with juvenile *S. borealis*, has

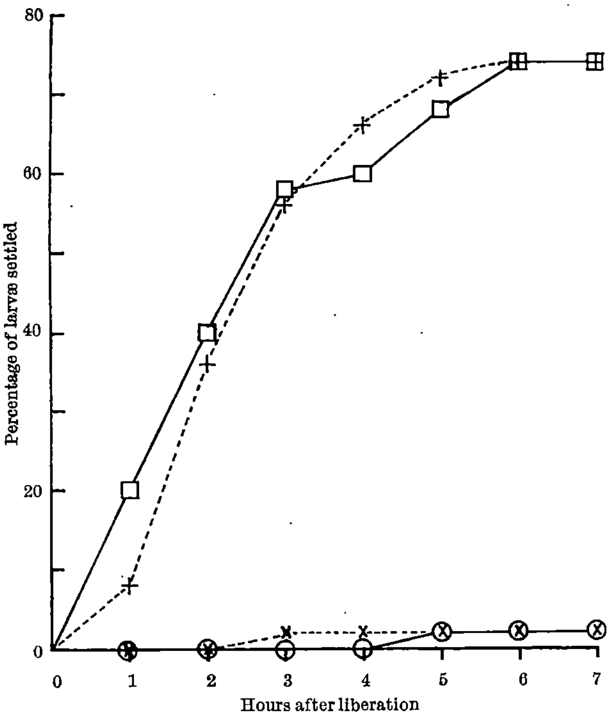

Fig. 1. Settlement of naturally and artificially liberated larvæ of *Spirorbis borealis* on *Fucus serratus* and *Corallina officinalis*. Larvæ settled on *Fucus*: □, naturally liberated; +, artificially liberated. Larvæ settled on *Corallina*: ○, naturally liberated; ×, artificially liberated

been found in the Swansea area only upon the red alga *Corallina officinalis*. Evidently it was desirable to find by experiment whether the larvæ of these forms choose their characteristic substrata.

Spirorbis borealis readily liberates larvæ in the laboratory[2,3]; but the other two forms referred to above do not. Their larvæ could be obtained in large numbers only by breaking the parents' tube and tearing up the chains of advanced embryos that were revealed. Many then hatched or were forced out of their egg capsules and swam towards the light. These larvæ seemed normal in appearance and behaviour. Before using them for experiments, however, larvæ were obtained in a similar manner from *S. borealis*. It was then possible to test the artificially liberated larvæ of this species against larvæ liberated naturally by their parents to see whether they were equally capable of metamorphosis and equally discriminating in their choice of a substratum.

In two parallel series of experiments, naturally and artificially liberated larvæ, in batches of about 25, were put into crystallizing dishes, each containing 100 ml. of sea water and a piece of *Fucus serratus*. After 24 hr., the numbers settled and metamorphosed were 355 out of 455 naturally liberated larvæ (78 per cent) and 229 out of 325 artificially liberated larvæ (70 per cent). The difference is not significant. The percentages are similar to that previously observed when larvæ of this species were presented with bare *Fucus serratus*[4].

In similar experiments, the percentages of larvæ settled were recorded after every hour. Those which had been artificially liberated settled just as early as the others (Fig. 1, upper curves). In parallel experiments pieces of *Corallina officinalis* were used instead of *Fucus* but few larvæ settled upon this alga (Fig. 1, lower curves).

In further experiments larvæ were offered a choice between pieces of *Fucus vesiculosus* and *Corallina officinalis* presented to them in the same dish. It was observed after 24 hr. that out of 200 artificially liberated larvæ, 142 had settled on *Fucus* and none on *Corallina*, whereas out of 200 naturally liberated larvæ 146 had settled on *Fucus* and 5 on *Corallina*.

It therefore appears that artificially liberated larvæ which are capable of swimming are as viable and discriminating in their choice of a substratum as naturally liberated larvæ. It will therefore be possible to use artificially liberated larvæ in experiments on the setting behaviour of other species of *Spirorbis*, particularly of the form which occurs so abundantly on *Corallina*. It seems unlikely that this form on *Corallina* is a young form of *S. borealis* since these experiments show that the larvæ of *S. borealis* do not settle readily on *Corallina*.

Similar methods of obtaining what might be regarded as prematurely liberated larvæ may be useful to workers engaged in anti-fouling research. It seems generally true that the ages at which crises in development occur are not fixed rigidly. Metamorphosis of a variety of planktonic larvæ can be postponed if they fail to find a suitable substratum[5,6]. Barnacle embryos may be retained as embryos by their parents for considerable periods, if there is little food available in the surrounding water[7-9].

I am grateful to Prof. E. W. Knight-Jones for his advice and criticisms.

Flash Lighting for Egg Production

The use of artificial lighting to extend day-length to 13–14 hr. is well established in commercial poultry-keeping as a means of stimulating the production of eggs in winter. Weber[1] claimed that similar increases in yield could be obtained by a 'shock-lighting' technique in which two 20-sec. flashes of high-intensity light, administered at 4.00 and 4.45 a.m., were the sole additions to natural winter daylight. Over the past seven years a series of experiments investigating the nature of the response to flash lighting has been carried out at Reading with the aid of funds provided by the Agricultural Research Council, and with the co-operation of the Electrical Research Association. These have confirmed that, although Weber's regime does not give the best results, pullets can be stimulated to high production of eggs by a variety of flash-lighting treatments.

It seemed at one time that flashes of light were quite as effective as normal extended lighting so long as they supplied the same total quantity of illumination—16 lumen hr./ft.^{2}/day—in addition to the natural daylight available. In the winter of 1956–57 a series of treatments, all providing this

Table 1. Flash Lighting Experiment: December 1956—March 1957

Treatment No.*	Wattage of lamps	No. of flashes	Duration of each flash (sec.)	Time of first flash	Interval between flashes	Egg production (eggs/bird/day)
1	1,500	3	20	3.00 a.m.	1 hr.	0·824
2	1,000	5	20	,,	20 min.	0·821

4	300	4–18†	10	14 hr. before sunrise	20 min.	2–8*	0·610*

* Treatments 2 and 4 significantly better than 1 and 3, $P < 0{\cdot}05$.
† Number of flashes varied to fill the interval between (sunset—14 hr.) and sunrise.

quantity of additional light, but varying widely in the intensity, number and duration of flashes, were tested and gave very uniform results (Table 1). Despite this uniformity, it remained difficult to reconcile the hypothesis of an 'optimum quantity' of light with any satisfactory physiological explanation, especially since the additional illumination is only a fractional increase on the relatively large, and very variable, amount of light provided by a winter day.

Farner *et al.*[2] (studying testicular development in sparrows) have postulated a light-sensitive mechanism capable of activation almost immediately upon the onset of lighting and remaining active for some time during the ensuing darkness. A similar mechanism, affecting the activity (rather than the growth) of the fowl's ovary, would allow an alternative explanation of the flash-lighting effect. If activation commences with a first flash at 3.0 a.m. and is maintained by subsequent flashes until daybreak, then the bird could be said to be 'illuminated' throughout this period. Thus the critical condition for the success of flash-lighting (for laying hens) would be an interval of 13–14 hr. between the first flash and sunset. A recent trial (see Table 2) has shown that the time of application of light can be altered so that it is no longer an effective stimulus (treatment 3); and that a much smaller quantity of light, applied at the right time, is sufficient to produce maximum response (treatment 4). The fact that Weber, working at Berne in Switzerland, found flash lighting from 4.0 a.m. to be satisfactory, whereas at Reading we have demonstrated that it is necessary to start at 3.0 a.m. to achieve results comparable with extended lighting, may be accounted for by the difference in the times of winter sunset at the two latitudes.

We can now argue that flash lighting does not differ in principle from the familiar techniques of poultry-house lighting. Although a satisfactory physiological explanation of the way in which light influences the rate of ovulation is no nearer, it is now possible to include the flash lighting of poultry as yet another aspect of photoperiodism in animals.

To define minimum standards for intensity, duration and number of flashes required to stimulate maximum production of eggs, allowing for possible interactions, would require an extensive series of trials. However, the assumption that 'high-intensity' illumination is required is probably false and a considerably smaller total quantity of light than was used in treatment 4 (shown in Table 2) might well suffice. Since none of the experiments at Reading has shown flash lighting to be superior to the standard 14-hr. day, and since the equipment needed for flashing is rather elaborate and the saving in cost of electricity is unimportant, there is little reason to recommend the use of this technique in practice. In special circumstances where it is necessary to stimulate egg production without encouraging other forms of activity in the bird, flash lighting may be of value.

It has long been assumed that maximum production of eggs in the fowl is attained under conditions of constant day-length, although Whetham[3] questioned this assumption more than twenty-five years ago and King[4] has recently published some evidence suggesting that continuously increasing day-length may be preferable. While we have recently shown[5] that onset of sexual maturity in the fowl is affected by changes in day-length and not by the absolute level of day-length, the problem of the light regime needed to elicit maximum rate of egg laying in the fowl requires separate intensive study. It is not necessarily true, as has sometimes been assumed, that conditions which are most favourable for bringing the gonads into a reproductive state are also the most favourable for maintaining a short interval between successive ovulations.

Occurrence of *Microsporum gypseum*, *Keratinomyces ajelloi* and *Trichophyton terrestre* in Some British Soils

In recent years many attempts have been made to confirm the belief that dermatophytes have a saprophytic existence in the soil. These investigations have disclosed the widespread occurrence of the pathogenic species *Microsporum gypseum* (Bodin) Brumpt[1-6] and the existence of the saprophytes *Keratinomyces ajelloi* Vanbreuseghem[2,5-7] and *Trichophyton terrestre* Durie and Frey[8].

A preliminary examination of some British soils has been made using the method developed by Vanbreuseghem[9]. The samples were collected by scraping into sterile boiling-tubes. They were then placed in Petri dishes and moistened with sterile distilled water. Short strands of autoclaved human hair were placed on the soil surface and the plates were left at room temperature (approximately 20–22° C.). Visible mycelial growth appeared on the hair in two to four weeks. Small pieces of mycelium and infected hair were transferred to plates of malt agar containing cycloheximide ('Actidione') 0·5 mgm./ml., penicillin 40 units/ml., streptomycin 40 units/ml. and potassium tellurite 0·36 mgm./ml.

The soils were collected from areas in and around Bath, Somerset, where clay on limestone predominates. Thirty samples were examined; of these, seven came from farmland and eleven were garden soils, the remaining twelve being from woodland, parkland, riverside and roadside banks and river gravel.

Results are summarized in Table 1.

Table 1

	Farm	Garden	Others
K. ajelloi only	1	9	1
K. ajelloi + *M. gypseum*	1	1	—
K. ajelloi + *T. terrestre*	3	—	2
Negative for these species	2	1	9

One of the farm soils which yielded *K. ajelloi* and *T. terrestre* contained cow hairs and another contained feathers. The conidia of these species were seen on direct microscopical examination of the disintegrating feathers in the latter sample.

Various other keratinophilic fungi which have not yet been identified were also encountered both in the presence, and in two cases in the absence, of the three known species. The ten soils from which no keratinophilic fungi were isolated included a mole-hill in a pasture, a recently ploughed field, a roadside bank and all the seven woodland soils examined.

Freemartins in Sheep

With cattle twins of opposite sex the female is in almost all cases infertile and shows varying degrees of masculinity, both in behaviour and in the morphology of the reproductive tract. Such females are known as freemartins. Swett *et al.*[1] consider that the freemartin condition is due to irreversible modification of the female by masculinizing secretions from the male fœtus. It is possible for any such secretions to pass between the two fœtuses as it has been known for some time that the bloods of twin calves are able to mix through anastomoses in the placental vessels[2].

Owen[3] and Owen *et al.*[4] have reported that most dizygotic twin calves are red blood-cell chimæras. They are born with, and often retain throughout life, red cells of dual origin. The same authors argued that since the life of red cells is short, red-cell precursors must be exchanged between the twins via the placental anastomoses during fœtal life and these precursors must establish themselves in the tissues of the opposite twin. It has been shown that the majority of dizygotic twin calves are tolerant to each other's tissues[5]. They will accept homografts of each other's skin, whereas grafts exchanged between calves of the same parentage but born at different times are rapidly rejected.

In a recent study in which attempts were made to induce a state of acquired tolerance in sheep, we used the fate of skin homografts as a criterion to determine if tolerance had been established. In the sheep, skin homografts are normally rejected and die within 10 days of grafting, whereas autografts are accepted by the host[6]. In the course of this study grafts were exchanged between sheep twins of opposite sex; in all, five sets of such twins were involved. Four of the five sets showed normal homograft reactions, the skin dying within 10 days, whereas the homografts on the remaining pair behaved as autografts. At the time of writing these surviving grafts are 245 days old, and both appear quite healthy, each being covered by an excellent growth of wool. The female of this pair shows abnormal development of the vulva and clitoris (Fig. 1), and although now more than two years old has never shown any signs of œstrus. She does in fact appear to be a freemartin.

Freemartins in sheep have only been reported sporadically[7,8]. The observations reported above provide further evidence for the occurrence of freemartins in

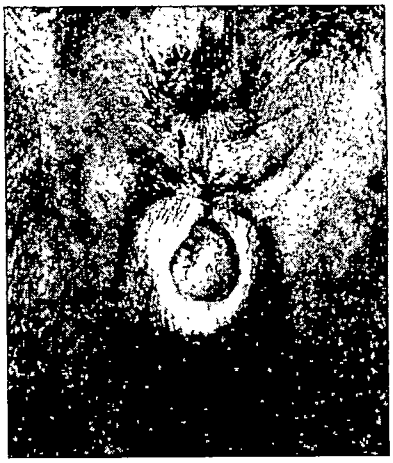

Fig. 1. Enlarged vulva and clitoris of female twin

sheep, and they suggest that a state of tissue tolerance may exist between the freemartin and her male twin.

We are indebted to Dr. T. R. R. Mann for reading and discussing the manuscript, and one of us (N. W. M.) was supported by a Science and Industry Endowment Fund administered by the Commonwealth Scientific and Industrial Research Organization of Australia.

Automatic Subdivision of Associated Populations

Consideration has been given in the past to the factorial analysis of qualitative data[1], including that particular form in which the attributes (presence-or-absence, yes-or-no) can take only the values 0 or 1, so that the correlation matrix is obtained from a set of 2×2 contingency tables[2]. Little attention has been paid to the valuable information to be obtained from the subdivision of populations of this latter type. Goodall[3], working with vegetation, pointed out that such populations are divisible into "homogeneous" groups, in which all associations are either indeterminate (a given attribute being 0 or 1 in all members of the group) or below a predetermined significance-level. Unfortunately, he elected to divide by reference to a criterion which is inefficient, and which tends to produce final groups capable of ambiguous recombination.

The problem is to find the attribute which, at each stage of subdivision, is most likely to reduce the residual associations to their lowest possible level. At first sight, an attractive solution would appear to be to divide on the attribute with the highest loading, irrespective of sign, on the first principal axis of the correlation matrix. However, although finding this presents no difficulty on an electronic computer, it involves not only calculating but also storing all the elements of the matrix, thus seriously reducing the space available for the basic data (that is, the specified individuals). A similar objection applies to the corresponding element of the first centroid axis. Furthermore, it is by no means certain that the resulting division is the best for all purposes. As has been pointed out elsewhere in connexion with the ecological application of the problem[4], Goodall's definition of a "homogeneous group" depends ultimately on a significance test, the simplest of which for such purposes is the calculation of χ^2 with Yates' correction. If this criterion is in fact used, a preferable solution is to divide by reference, not to the correlation matrix, but to the corresponding contingency matrix. The correlation coefficients (r) can then all be taken with the positive sign, and the attribute with the highest $\Sigma\ |r|$ will necessarily be the attribute with the highest loading on the first centroid axis of the contingency matrix. (We prefer to use $|r|$ rather than r^2, the mean-square contingency itself, since it provides a closer analogy with factorial analysis; experience suggests that this does not discernibly reduce the efficiency of subdivision.) Since the $|r|$ values can be summed as they are obtained, it is necessary to provide only as many storage locations as there are attributes. Except for very large projects, ample space is thus available for both programme and data, and the subdivision can be made fully automatic.

We have therefore prepared, for the Ferranti 'Pegasus' computer, a programme which, from the specifications of all the individuals concerned, will carry out completely automatic subdivision into groups homogeneous at the $P = 0{\cdot}05$ level of significance. The highest χ^2 encountered during the examination of any group is printed out, thus permitting cross-comparison of all intermediate groups; and provision is made for disregarding any attributes which it is desired to exclude from the analysis. The programme exists in two alternative forms: the first will process up to 3,360 individuals specified by not more than 38 attributes, the second up to 1,680 individuals specified by not more than 76 attributes.

The resulting information may be used in several ways. Most important is the study of the structure of the homogeneous groups themselves, with particular reference to the disposition of those attributes not specifically used for subdivision. Secondly, as these latter attributes are inherently likely to be of importance in any subsequent factorial analysis, the fact that they are already known may well facilitate decisions on the placing of hyperplanes; in fact, we suspect that in some cases sufficient information may be obtained from the subdivision to render the far more laborious factorial analysis unnecessary. Lastly, if, as in ecological work, the individuals are of known distribution in space, the groups can be plotted on a map.

Salt Excretion in Marine Birds

In connexion with recent research on salt excretion in marine birds[1,2] the following observation which I made some twenty-five years ago may be of interest. While cruising in a yacht far from land in the northern North Sea, I often used to watch lesser black-backed gulls as they soared above the ship or were perched on the mast head. I was very puzzled to account for a regular rain of drops of water which each bird shook at intervals from the tip of its beak. This was evidently salt excretion in action, and I know of no similar published account.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Psychologist (male, with a first- or second-class honours degree with psychology as the main subject or equivalent qualification) at the Ministry of Supply Clothing and Stores Experimental Establishment, Farnborough, Hants, to work in the Applied Psychology Section on the design of military equipment aiming at greatest efficiency, comfort and safety in its operation—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting Ref. G.409/8A (December 23).

Scientist (Mathematician, Physicist or Engineer) (with at least a second-class honours degree or equivalent in an appropriate subject, and suitable research experience) at Dounreay Experimental Reactor Establishment, to lead a team responsible for mathematical physics calculations in connexion with the Fast Reactor and laboratory investigations of associated problems—The Recruitment Officer, United Kingdom Atomic Energy Authority, Industrial Group Headquarters, Risley, Warrington, Lancashire, quoting Ref. 2797/T (December 29).

Lecturer (Veterinary Surgeon) in Veterinary Pathology—The Registrar, The University, Liverpool (December 30).

Library Assistant (Special Grade) (honours graduate, preferably with a diploma in librarianship and some previous library experience) —The Secretary of University Court, The University, Glasgow (December 31).

Chair of Nuclear Engineering—The Registrar, The University, Manchester 13 (January 1).

Demonstrators in Biochemistry and Nutrition and/or Physiology in the Faculty of Rural Science—The Registrar, University of New England, Armidale, New South Wales, Australia (January 1).

Secretary to the British Trust for Ornithology with offices at Oxford, for duties which include the supervision of field investigations, financial and office administration, correspondence with membership, attendance and speaking at meetings, and public relations—The Honorary Secretary, R. K. Cornwallis, British Trust for Ornithology, Bleasby Grange, Legsby, Market Rasen, Lincolnshire (January 1).

Assistant in Research (with an appropriate honours degree and preferably an interest in animal genetics) in Animal Physiology—The University, Downing Street, Cambridge (January 7).

Senior Technician (with experience in the maintenance of colonies of animals) in the Departments of Biological Sciences and Pharmacy, to take charge of the animal house—The Registrar, Bradford Institute of Technology, Bradford 7 (January 7).

Assistant Lecturer or Lecturer (with an honours degree in architecture and special knowledge of the application of scientific research to building construction) in the Department of Building Science—The Registrar, The University, Liverpool (January 10).

Chair of Geology—The Secretary, The University, Exeter (January 17).

Senior Lecturer or Lecturer (with registrable medical qualifications) in Anatomy at the University College of the West Indies—The Secretary, Senate Committee on Colleges Overseas in Special Relation, University of London, Senate House, London, W.C.1 (January 26).

Assistant Lecturer in Applied Mathematics—The Secretary, The Queen's University, Belfast (January 30).

Lecturers (2) (preferably, but not necessarily, experience of research work in experimental or theoretical nuclear physics) in the Department of Physics—The Registrar, The University, Liverpool (January 31).

I.C.I. Research Fellows in Biochemistry, Chemistry, Engineering, Pharmacology, Physics, Chemical Technology or Chemical Engineering—The Secretary, The University, Edinburgh (February 16).

I.C.I. Research Fellows in Chemistry, Biochemistry, Physics, Engineering, Chemotherapy and related subjects—The Secretary, Academic Council, The Queen's University, Belfast (March 1).

Assistant, Grade B (with a good degree) at the Municipal College of Technology and Commerce, Bournemouth, to teach mathematics principally to G.C.E. advanced level—Chief Education Officer, Town Hall, Bournemouth.

Assistant Biochemist (B.Sc.) in the Fife District Laboratory, Windygates—The Medical Superintendent, East Fife Hospitals Board of Management, 243A High Street, Kirkcaldy.

Associate Professor (with experience in both teaching and research) of Electrical Engineering in the School of Engineering, Carleton University, Ottawa, Ontario, Canada—Dr. J. G. Malloch, Scientific Liaison Officer, National Research Council of Canada, Africa House, Kingsway, London, W.C.2.

Biochemist (with an honours degree in chemistry or biochemistry and preferably with experience of biochemical research), to carry out research on metabolic diseases of farm animals—The Secretary, Animal Diseases Research Association, Moredun Institute, Gilmerton, Edinburgh 9.

Curator (between the ages of 25 and 35, at least B.Sc. zoology, preferably with entomological leanings) of the Nyasaland Museum, to build up a museum exhibition from available collections and from collections to be made—The Secretary, Museum Board of Trustees, The Secretariat, Zomba, Nyasaland.

Ecologist (with a good honours degree in botany and at least two years postgraduate experience or training in ecological survey methods including aerial photograph interpretation) in the Ministry of Agriculture, Northern Region of Nigeria, to be responsible for all vegetation aspects of the ecological, soil and land-use surveys currently being undertaken by the Northern Region Ministry of Agriculture—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.63/408/012.

Physicist or Chemical Engineer (with a good honours degree and preferably some experience of research) in the Blast Furnace Laboratory, Imperial College of Science and Technology, London, S.W.7, for laboratory and theoretical work on heat transfer and combustion problems—The Personnel Officer, British Iron and Steel Research Association, 11 Park Lane, London, W.1, quoting "H.T.1".

Scientific Officer (preferably Botanist/Physiologist) in the Pomology (Horticultural Botany) Department, for work mainly on selective weed control; and a Librarian—The Secretary, Scottish Horticultural Research Institute, Mylnefield, Invergowrie, by Dundee.

Statistician (graduate, with suitable qualifications and experience, preferably including field trials)—The Secretary, National Institute of Agricultural Botany, Huntingdon Road, Cambridge.

Technician (preferably with previous experience) in the Chemistry Laboratories—The Secretary, Royal Holloway College (University of London), Englefield Green, Surrey.

Technician (with experience in chemistry, and preferably some knowledge of glass-blowing) in the Biochemistry and Chemistry Department—The Secretary, Guy's Hospital Medical School, London Bridge, London, S.E.1.

PLANNING OF EXPERIMENTS

by

D. R. COX

(Reader in Statistics, Birkbeck College, University of London)

315 *pages* *Illustrated* 60*s. net*

In this book the fundamental ideas of modern work on the statistical aspects of experimental design are presented in full. Examples are chosen from a wide variety of topics, such as: physics, industry, agriculture, zoology, psychology, medical and dental research.

BIOCHEMICAL PREPARATIONS

(Volume 6)

Editor-in-Chief:

CARL S. VESTLING

114 *pages* *Illustrated* 42*s. net*

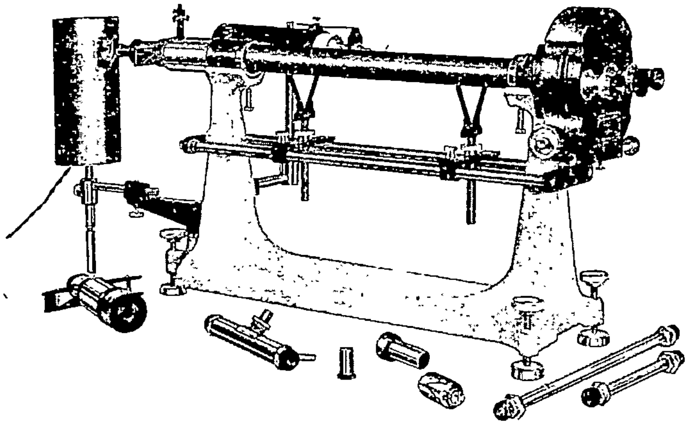
The latest volume in a notable series which has received widespread recognition as an important contribution to the biochemical literature. Accurate, highly detailed, and well-annotated, the volumes in the series have proved to be invaluable time-savers for research workers.

37 ESSEX STREET, LONDON, W.C.2

PRECISION INSTRUMENTS

Polarimeter Model A

This instrument gives the highest degree of accuracy with divided circle on glass reading to 0·01 degree



- Circle centre on ball bearings.
- Easily removable trough.
- Divided drum replacing verniers.
- Stationary observation telescope.
- Circle reader enlarging image of scale.
- Slow motion adjustment always in action.
- Suitable, with additions, for measurement of rotatory dispersion.

This polarimeter has been supplied in large numbers both in this country and abroad and has always been acclaimed as being of advanced design and workmanship.

ALLOCATION OF FUNDS FOR RESEARCH IN BRITAIN

ONE of the most important chapters in the recent report from the University Grants Committee on "University Development 1952–57" is that in which the Committee discusses the question of scientific research. After considering the balance between research and teaching, clear warning is given that, even if a reasonable proportion is maintained between them, balanced development of the work of the universities will only be ensured by unceasing vigilance that sponsored research and other outside support is not accepted on terms inconsistent with that development. The report then discusses in some detail the respective functions of the University Grants Committee and the research councils. This passage alone raised the whole question of the effective organization and management of the scientific effort of Britain within the pattern of values that characterizes our society and the peculiar requirements of science. It is clear that the University Grants Committee is deeply concerned with both the manner in which new lines of scientific work should be administered and the sources from which they should be financed.

The importance of this particular aspect of the subject has been emphasized recently by the criticisms of the Committee of Public Accounts of the Jodrell Bank radio telescope project and the situation which has led the University of Manchester to launch an appeal to raise the £150,000 still required to meet the costs. More generally, it was indicated by Prof. A. C. B. Lovell in the fourth of his Reith Lectures, on November 30, when he discussed formally the issues involved in the support of financial research by the State. Prof. Lovell made no direct reference to the Jodrell Bank situation, or to the proposal for a British programme of specialized space research which is understood to have been recommended by the Royal Society Conference on Space Research. It was rather the magnitude of the expenditure required to support such lines of research and the sacrifices inevitably demanded elsewhere with which he was concerned. Sacrifices may in fact well be demanded, if not in real standards of living, at least in some of the non-essentials that are too lightly taken for granted, without regard to the continuing scientific and technical effort through which alone they have been achieved.

Prof. Lovell did not stray into the field of politics or even of sociology; it was only obliquely that he indicated that a choice may have to be made between defence and security as at present conceived and the continued existence of mankind. Granted, however, that the transfer of effort and resources from the demands of defence to the constructive purposes of peace would release more than sufficient for the prospective needs of civil research and development, no statesman of any political party could contemplate such a step or propose the sacrifices that would be entailed or required by alternative measures without himself first very clearly apprehending what is involved from the point of view of science and technology, and then taking the most positive and energetic steps to prepare the electorate for whatever changes and sacrifices are required. As one first condition of any such attempt, both political parties must cease all attempts to make party capital out of the situation.

There is thus pre-supposed a very considerable campaign of education at high levels before we can hope to see any Government proposals allocating resources for scientific and technological development on the scale now desirable. Parsimony is not to be cured quickly, and there is always the over-riding problem of balance. Even a programme of £15 million a year over four years for space research is not to be approved lightly and without regard to possible repercussions on other fields of scientific and technological research; and once a programme has been approved, there is continuing need for public understanding and support. Sir Eric Ashby rightly remarked in his recent book "Technology and the Academics": "That a university should interpret itself to its patrons and explain its need for autonomy is . . . a necessary feature of its adaptation to the scientific revolution", and the comment is equally relevant to the independent research institutions and the research councils.

Prof. Lovell clearly recognizes this need for exposition and interpretation, and, although the administrative aspects were outside his survey, he just touched on the conditions of freedom and independence in which alone scientific research can flourish and which it should be a prime objective of administrative organization and policy to foster and preserve. Long-term dangers are inseparable from the support of fundamental scientific research by the State on a large scale, and the delicate and perilous situation which faces university administrators in Britain is without precedent. Failure to absorb these great new scientific projects into a framework where the traditional university freedom of inquiry can flourish would, he believes, be fraught with grave dangers to scholarship and scientific education.

All this is very clearly in the mind of the University Grants Committee, and in this perspective the actual balance of effort between teaching and research appears to be a secondary issue. In any event, the Committee rejects the view that the balance could be determined precisely, or even that the cost of research in universities can be estimated closely. It suggests that the cost of scientific research in universities in science, technology, medicine and agriculture was about £16 million in 1955–56 and probably £20 million in 1957–58, part of the difference being due to an increase in academic salaries. Of this amount, £2,307,000 in 1955–56 was received for research sponsored by bodies outside the universities,

£1,246,000 coming from the research councils and other Government departments.

In 1956–57 these figures rose to £2,683,000 and £1,377,000, respectively, and although they do not cover all the expenditure which could be apportioned to research if the whole of the recurrent expenditure of the universities were divided between the various activities carried out in them, the University Grants Committee appears to be justified in its view that government departments and agencies are not making excessive demands on universities in the matter of sponsored research. Research which is financed by the Council for Scientific and Industrial Research, the Medical Research Council, the Agricultural Research Council and the Nature Conservancy is generally free from these dangers, since it follows lines which are selected predominantly by the university research workers themselves ; hence the Committee is disinclined to extend its own responsibilities for financing academic research.

Without some clarification of this point, however, the views of the University Grants Committee may not be generally shared. The re-organization now proceeding under the Council for Scientific and Industrial Research is being closely watched, and it is too early to feel any real assurance that such research will be supported more generously in the future, or even that the Council is the most appropriate means through which State grants should be made for fundamental research : the Jodrell Bank episode alone would suggest reserve on that point. Again, it cannot be suggested that support of the Nature Conservancy has been other than meagre, amounting almost to starvation where research is concerned.

Nevertheless, the University Grants Committee emphasizes a vital point in directing attention to the desirability of research workers in universities (or indeed in independent institutions anywhere) being able to obtain support from more than one source for lines of research which they wish to pursue. This is particularly true in respect of newly emerging lines of research, and though a Government source of finance cannot be expected to provide the same continuity or even support on the same scale at the start for the growing points as the independent foundation, there is sound reason for public support, in this way providing funds alternative to general university income. The problem is rather as to the means by which such support is most appropriately and effectively made available.

On this point, the University Grants Committee lays down very clearly its reasons for declining to be the source of earmarked funds for new lines of research. First, it insists that if university autonomy is to be a reality, it must continue to minimize its intervention in the allocation of funds within universities, which already receive 70 per cent of their income from the Committee. Secondly, it stresses the value of direct relations between a body supporting particular lines of research and the individual research worker and university department, as is possible with the research councils and the Royal Society. Again, the membership of the research councils and their committees, together with that of the Government Grant Boards of the Royal Society, includes the most experienced workers in the respective fields which they cover. Quite apart from the fact that the University Grants Committee, while exercising its present functions, could not give the same expert scrutiny and assessment to research projects without developing an unwieldy organization, the Committee makes the vital point that it is undesirable that such a single governmental colossus should bestride the whole university world. Finally, the universities have no monopoly of research, and it is necessary that any agency established to stimulate research in any field should be in a position to survey all the research in that field, decide whether any particular line of research is best pursued in a university or in some other establishment, and maintain due contact between university and other research.

This value of diversity of sources of finance is so great as to outweigh the possible danger of overlapping ; nor is it likely that any serious gaps in the field of science will be left uncovered between the research councils and the Royal Society. Provided that reasonable funds are made available to them, the informal contacts already indicated should take care of both dangers, and where the independent foundations or industry do not also intervene to cover gaps, they are unlikely to escape the scrutiny of university departments ; though it is admitted that the question of borderline fields and interlocking disciplines may require special attention. It may be recalled that Dr. L. V. Berkner, in the United States, has likewise stressed the importance of a diversity of sources of support for academic research, and the same point was made in the National Science Foundation's report on government–university relations, which outlined some principles recommended for the conduct of scientific research and development sponsored by the Federal Government in the United States.

The University Grants Committee suggests that the very success of a branch of research supported by a research council may create a problem of much greater practical importance when a topic previously receiving little recognition develops into a branch of learning of such importance as to require representation within the established departments of a university. Virology, chemical microbiology and biophysics started in this way ; and it is clearly desirable that a line of original scientific work which has proved itself should be financed in the ordinary way from the general university income, and that the university should accept full responsibility for it instead of regarding it as an extraneous activity. The Committee is therefore making arrangements with the research councils to enable universities to assume financial responsibility for work that has hitherto been financed by a research council, when it can be regarded as established and ripe for transfer.

Thus flexibility, even a dynamic approach, are no less important than informality in whatever admin istrative arrangements are concerted for the support and co-ordination of research ; and the recent annual report for 1957–58 of the Advisory Council for Scientific Policy*, which has followed the report on university development, indicates that the Advisory Council is as aware of this as is the University Grants Committee, and that within its own framework it is seeking to foster the conditions in which science and learning best flourish. Indeed, whatever the level of State support for scientific and technological research, whether or not the nation derives the maximum return from that investment depends primarily on whether the right conditions are provided, including not merely equipment but also the supporting technicians and facilities such as libraries and information services in the broadest sense. With Britain's comparatively limited resources, it is the more important that the fullest possible use should be made of the scientific man-power and equipment available ; and it might well be prudent to give greater attention to this point at the moment rather than to open up new fields prematurely.

In its report for 1956–57, the Advisory Council on Scientific Policy indicated that it proposed to consider further whether the existing arrangements for financing pure research in the universities were as satisfactory as they should be ; and it was at the request of the Advisory Council that the University Grants Committee reviewed the nature and extent of its responsibility for financing university research and the part which the research councils and the Royal Society should also play. The reasons which led the University Grants Committee to conclude that the research councils and the Royal Society have an essential part to play, and that its own responsibilities should not be extended to cover it, are those on which its objections to being the source of earmarked funds for new lines of research are based. The Advisory Council on Scientific Policy sets forth the argument at length in its current report, and records that these considerations convinced the Council that the advantages of alternative sources of support for research outweigh any administrative disadvantages they entail. In this connexion it again stresses the value of the financial support given to pure research by the charitable foundations and by industry.

Quite apart from the addition thus made to the total expenditure on university resources, the existence of these alternative sources of support minimizes the danger that entirely novel ventures may go unsupported because of their very unorthodoxy. While the Advisory Council is primarily concerned to see that research workers with promising ideas are able to develop their researches, and that the best use is made of university staff and facilities, it discusses further the detection and filling of gaps in the research effort. This is one of two problems in the existing system that requires special attention : to the other—that of the transfer of responsibility for a line of research once well established—the University Grants Committee, the research councils and the Royal Society, as has been seen, are already giving continuing attention.

The Advisory Council points out that it is the established practice of the research councils to review both the work they themselves support and that being carried on by the universities and other bodies, with the view of identifying gaps in the field and concerting measures to anticipate future trends. From time to time committees of the Royal Society also review the whole range of research activities in science, with the view of detecting and directing attention to lines of research which do not appear to be receiving adequate support or are otherwise neglected. Nevertheless, there are fields of research which do not fall clearly or wholly within the sphere of interest of any one of the research councils, and in considering these the Advisory Council concludes that there is a danger that borderline subjects, and especially those calling for a team of experts from different disciplines, might fail to get the attention which, in the national interest, should be devoted to them. The Advisory Council mentions research into irrigation problems, ecological and physiographical studies and certain aspects of invertebrate physiology ; and there appears to be particular danger that this may arise with some of the work for which the Department of Scientific and Industrial Research has been responsible, if only as a result of the criticism to which the Department has recently been subjected.

The Advisory Council considers it important that a research council should not be restricted by too rigid a definition of its particular field, but should be allowed to expand its ambit to take account of widening interests as these arise. Clearly the research councils and the Royal Society have already the arrangements for informal consultation which, moreover, broadly meet the fundamental criterion that the identification and selection of programmes or projects for research should be in the hands of the scientists themselves. This should facilitate the identification of gaps ; but the Advisory Council does well to point out that it is vital that these arrangements should be kept under constant review and, if necessary, improved to guard against the danger of borderline subjects not receiving support.

While, therefore, such a system of multiple sources for financing research as exists in Britain provides reasonable safeguards both for academic autonomy and the freedom of the scientist and technologist to select and pursue his research objectives, it throws a considerable strain on administrative arrangements. Effective co-operation between the various grant-giving bodies is essential both to secure adequate finance and to prevent serious gaps developing in the research effort. Moreover, it does not appear that by itself it is sufficient to ensure that adequate support is forthcoming from Government sources.

That last is the only broad conclusion that can be drawn from a series of recent reports from, for example, the Committee of Public Accounts and the Select Committee on Estimates, particularly those relating to Treasury control, the Department of

---

* Annual Report of the Advisory Council on Scientific Policy, 1957–58. Cmnd. 597. Pp. 22. (London: H.M. Stationery Office, 1958.) 1*s.* 3*d.* net.

Scientific and Industrial Research and the construction of the radio telescope at Jodrell Bank. It is not simply that we have yet to devise an appropriate system of public accounting for the expenditure of public funds on large scientific and technological products. There is also the parallel problem of interpretation and exposition, so that Parliament and public understand clearly what is being done and what is needed, and are prepared to supply the requisite public funds.

In his remark, "The Civil Servant who is at the same time fellow of All Souls is the best guarantee one could have for the autonomy of British universities", Sir Eric Ashby gives a clue as to where the need is most likely to be met ultimately—in an adequate system of public education which will ensure that the ordinary citizen, whatever his or her occupation, has some understanding of what science is about, and that the administrator or Minister or member of Parliament is at least capable of appreciating the scientific issues in questions of public policy which are put to them. This lies, of course, outside the orbit of the Advisory Council, except in so far as its support of technological education and of the teaching of science contribute to that end. Nevertheless, the Advisory Council's eleventh report provides more encouraging evidence than recent reports that it is succeeding in getting greater attention given to varied ancillary factors which, in the aggregate, are of importance in ensuring Britain gets the maximum benefit from whatever resources in man-power and equipment are allocated for scientific and technological research.

CENTENARY OF GRAY'S ANATOMY

Gray's Anatomy : Descriptive and Applied

Edited by Prof. T. B. Johnston, Prof. D. V. Davies and Prof. F. Davies. Thirty-second (centenary) edition. Pp. xxiii + 1604 + 32 plates and 1,277 figures. (London and New York : Longmans, Green and Co., Ltd., 1958.) 126*s*. net.

THE publication of this centenary edition of "Gray's Anatomy" is a unique event, for no other medical text-book has been published under the same title for so long a period. During its life the book has more than doubled in cost but its size has changed from 750 to 1,604 pages, the illustrations from 363 to 1,309 in number; the medical curriculum has broadened, and there is an outcry against many features of pre-clinical teaching and of anatomy in particular. The outcry continues unabated but not unheeded; for twenty years, indeed longer, there has been a steady decline in the amount of detailed knowledge required of pre-clinical students, and increasing emphasis has been laid on principles of functional anatomy. However, structure and function should never be divorced, and generalizations become meaningless if the evidence on which they are based is not available. The incidence of diseases and the appearance of pathological lesions are changing with social conditions and the advent of antibiotics and chemotherapy, but sound diagnosis is still based on accurate observation and evaluation of the normal and of departures from it; and potent drugs can, and alas do, produce permanent disability if injected into main nerve trunks. Certain of the despised minutiæ provide a key to understanding normal and disordered function; the structure of the renal tubules and their blood supply are a case in point. The less information the student is required to remember, the greater is the need for a reliable reference book.

The editors have gone far towards meeting this requirement. The approach to the subject is systematic, but not unfunctional; the salient anatomical features are summarized and their functional significance is stressed in introductory chapters which engender a sense of proportion in the reader's mind. Those preceding the sections of arthrology, myology and neurology are noteworthy, although Fig. 801 in the latter is misleading. The basic features of histology are given with masterly brevity in 54 pages, and the section on embryology relieves the student from the necessity for buying a separate text-book. The minutiæ, as always, are relegated to small print. The few new terms introduced by the Nomina Anatomica, Paris, 1955, are listed and the editorial board "have taken full advantage of their freedom to translate the Latin forma into its English equivalent", and where the Paris term differs from the Birmingham revision the latter has been given in parentheses for the first occasion on which the structure has been mentioned. Loyalty to the decision to adopt this terminology has forced the use of the undesirable and illogical term 'syndesmology' for 'arthrology'. There are numerous references to original papers, many published within the past five years and several as recently as 1956; it was therefore surprising to find no mention of the work of Sholl on the cerebral cortex.

New illustrations include excellent photomicrographs of the cyclical changes in the endometrium and Weigert-Pal preparations of the brain stem, additional X-rays of the wrist and knee joints, and four electron micrographs which remind us of the widening field of cytology. The machine-finished paper, which has been used for the first time, enhances the beautifully clear type and illustrations, a few of which are marred by crudeness of colour and errors of over-printing. The over-stylized drawings of the thoracic skeleton and ligaments of the lumbar spine reappear, and some drawings of cross-sections of limbs suffer on comparison with previous editions by being left uncoloured. Few typographical errors have escaped the proof readers. The editorial board is to be congratulated most warmly on the care and skill expended in the extensive re-editing. This up-to-date book can be recommended unreservedly to medical students, who will find it of value throughout their careers. RUTH E. M. BOWDEN

NOMINA REJICIENDA

International Code of Nomenclature of Bacteria and Viruses

Edited by the Editorial Board of the International Committee on Bacteriological Nomenclature. Pp. xxii + 186. (Ames, Iowa : Iowa State College Press, 1958.) 3.50 dollars.

ARE bacteria a class of plants, Schizomycetes, distinguished by the fact that they reproduce exclusively by simple fission, or are they not ? The name has one virtue, one of the two allowed by

Mortimer Batten to the song of the kingfisher: nobody hears it. Because nobody, including the authors of this book, ever uses it; but the taxonomic system, of which the book is intended to be the instrument, hinges upon its validity.

Apart from the purely biological questions of the mutual and external relationships of bacteria, in which I have myself been interested, it has recently been proved that in the significant characteristic of cell-wall composition bacteria are *sui generis*. They are not plants, and they most decidedly do not confine themselves to simple fission.

There is no question that bacteria require a code of nomenclature, but there is every reason why this should be an effectively separate code, so that we may be spared such exercises as the consignment to limbo of well-known and useful names, *Listerella*, *Pfeifferella* or *Phytomonas*, on the ground that they have prior application to genera of protozoa. *Fritillaria* is both a plant and a pelagic ascidian, but this has not been the cause of any confusion. Greater confusion is likely to be caused by entitling as 'fungus' (*Malleomyces*) an organism that has more in common with the pseudomonads, or by substituting for a name invalidated by prior application to a genus of protozoon, one that has prior application to a green plant (*Listeria*).

The book is mainly concerned with rules for the nomenclature and valid publication of bacterial groupings. There is one rule of primary importance that is not stated, however: that any name, to be valid, must be accompanied by a description which enables the organism in question to be recognized. The firm application of such a rule would obviate the necessity for laboriously working out the priorities of all names published since 1753, since nine-tenths of them would be automatically invalidated.

Not that considerations of priority would appear to have over-riding force in these matters. *Bacterium coli* has many years priority over *Escherichia coli*, nor am I aware of any difficulties arising from its use, but not only does Opinion 15 forbid us to use it, it also informs us: "This Opinion is final unless revoked or modified by action of the International Committee on Bacterial Nomenclature". I wonder how much hope there is of finding that *Escherichia* has prior application in a genus of protozoon.

This part of the Code does not concern itself with the attachment of binomials to viruses, and perhaps that is not wholly a bad thing. K. A. Bisset

MARINE BIOLOGY IN SOUTH-EAST AFRICA

A Natural History of Inhaca Island, Mocambique

Edited by Dr. William Macnae and Dr. Margaret Kalk. Pp. v+163+11 plates. (Johannesburg: Witwatersrand University Press, 1958.) 42*s*.

When the late Prof. C. J. van der Horst went to Johannesburg about twenty-five years ago he looked for a suitable place to conduct classes in marine biology and to undertake research. He found Inhaca Island, and his dream of a marine station there (the only one in the whole of South Africa) was realized in 1951, when the Portuguese Government established the laboratory with the collaboration of the University of the Witwatersrand.

Inhaca Island, which lies on the seaward side of the Bay of Lourenço Marques (Delagoa Bay) in latitude 26° S., is well placed, and is of particular interest from a biologist's point of view, "because it is close to the southernmost limit of the fauna and flora characteristic of tropical east African shores and at the same time it is the northernmost limit of the littoral fauna and flora of Natal and south-eastern Africa. The bulk of the fauna and of the algæ and intertidal marine flowering plants is of tropical origin".

This volume, which has been edited by Dr. W. Macnae and Dr. M. Kalk, is the work of many South African biologists who have visited Inhaca and who have contributed chapters on their special groups. In this way, during the short time the station has been in existence, a formidable list of species has been recorded and included here. The greater part of the book describes the marine life, but there are digressions on the land fauna and on the terrestrial vegetation. For botanists, there are chapters on the ecology of algæ and the sea grasses, with excellent check lists both of these and of the flowering plants.

The general ecology of the shore is well described by Dr. Kalk, and there is a great variety of intertidal habitats from the coral reef (an impoverished one) on the exposed seaward side of the Island, through numerous and often sheltered ecological niches, with substrata ranging from hard rock to sands of different compositions and to thick, water-logged mud in the mangrove swamps. These habitats are rich in species, and have, for example, yielded Prof. J. H. Day no fewer than 160 polychaetes. The major groups, molluscs (Dr. Macnae), crustaceans (Dr. Kalk), echinoderms (Prof. B. I. Balinski) and the fishes (Prof. J. L. B. Smith), are well represented, and the accounts are eminently suitable for the visiting student.

Prof. P. H. Boshoff describes the constitution and the development of the local coral reefs and it seems that species are few and limited to eurythermic ones. *Acropora*, for example, is represented by seventeen species—more than a hundred have been described—so that Inhaca may be a good place to ascertain whether even this reduced number possess distinct biological characteristics, or whether they are merely ecological variants of two or three species. It is perhaps relevant to mention here that the museums of the world contain extensive dry collections of such problem genera bearing a multiplicity of names, the significance of which, if any, remains to be elucidated through study of the living coral.

Keys are provided for the major groups and a habitat list indicates where the intertidal species can be found. Some groups of invertebrates are not included, notably Protozoa, Porifera and Polyzoa. In the brief account of coelenterates, *Muggiaea*, the name of a siphonophore, has been used for a scyphomedusa, and it should be noted that the chondrophores *Velella* and *Porpita* are pelagic hydroid colonies and are no longer considered to be siphonophores. Venomous invertebrates are not adequately noted for the student; there is no mention of the severe sting caused by the hydroid *Lytocarpus*, and the only cone shell specifically noted as causing a severe sting is *Conus ebraeus*, although two other species recorded from Inhaca, *Conus textile* and *C. geographus*, are both well known for their ability to produce fatal stings in human beings.

These minor defects should not be allowed to obscure what has been done; for the student and prospective research worker, this well-illustrated natural history *cum* fauna list is a remarkable achievement and provides a very good introduction to what Inhaca has to offer.

W. J. Rees

HETEROCYCLIC CHEMISTRY

Current Trends in Heterocyclic Chemistry

Proceedings of a Symposium held at The John Curtin School of Medical Research, Australian National University, Canberra, 2nd–4th September, 1957, under the auspices of the Chemical Society. Edited by A. Albert, Dr. G. M. Badger and Dr. C. W. Shoppee. Pp. ix+170. (London: Butterworths Scientific Publications; New York: Academic Press Inc., 1958.) 30*s*.; 5.50 dollars.

Les Heterocycles Oxygenes

Colloques Internationaux du Centre National de la Recherche Scientifique, 64 (Lyon, 5-10 September 1955). Pp. 390. (Paris: Centre National de la Recherche Scientifique, 1957.) 2,500 francs.

The 1,2,3- and 1,2,4-Triazines, Tetrazines and Pentazines

By John G. Erickson, Paul F. Wiley and V. P. Wystrach. (The Chemistry of Heterocyclic Compounds: a Series of Monographs, Vol. 10.). Pp. xii+261. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1956.) 9.50 dollars.

"CURRENT Trends in Heterocyclic Chemistry" records the papers which were read during a three-day symposium held in Canberra in 1957, and gives, in addition, a verbatim account of the discussions which followed each paper. The title, however, covers an immense field of current work, which clearly could not be adequately represented in twenty comparatively short papers: moreover, the authors have naturally tended to discuss work in which they were particularly interested. The result is that the volume is almost exclusively devoted to heterocyclic derivatives of nitrogen, with an occasional reference to those of oxygen and of sulphur. A more suitable title would have been "Some Current Trends", or alternatively "Current Australian Trends" (as Prof. A. Albert emphasizes in his introduction).

The papers are of considerable interest, and the fact that each is short and devoted to a strictly limited topic will make them particularly attractive to students. Furthermore, they are not limited to the pure organic chemistry of the heterocyclic systems: the physical side appears in papers such as "Physico-Chemical Studies on Solubilized Porphyrins" by J. N. Phillips, and "Spectrum and Bond-Type in Metalloporphyrins" by J. E. Falk and R. S. Nyholm, and the biochemical side in "Biotransformation Products of ^{14}C-Labelled Codeine and Morphine" by T. K. Adler.

The extent to which these studies of the nitrogen heterocyclic systems have been carried forms a striking testimony to the vigour and enthusiasm of the Australian chemists, more particularly Prof. Albert, the organizer and chairman of the symposium.

One might, however, question the advisability of including in volumes of this type complete reports of the discussions which follow the papers. During an informal discussion many quite minor points can often very usefully be raised, but some participants would hesitate to raise them if they knew that their queries would be recorded in full and published. Reports limited to the major points would avoid this factor.

"Les Heterocycles Oxygenes" contains thirty papers on heterocyclic derivatives of oxygen, and although the majority of the authors are French chemists, the other authors come from many lands and have thus made the colloquium truly international. Many of the papers differ from those usually found in reports of symposia in that they contain a fair amount of new experimental material, with yields, physical data, analyses, etc., of the compounds described: furthermore, each paper is followed by an apparently verbatim account of the discussion it provoked, and the complete collection therefore forms a volume of impressive size.

The papers on purely organic aspects deal mainly with the preparation of derivatives of furan and pyran, and the use of these derivatives in further synthetic work: the derivatives of pyran which receive most attention are naturally those of chroman and of flavone. Several papers deal with the isolation of cyclic oxygen derivatives from plant sources, and with the structure of these derivatives. The last paper discusses the biological action of certain heterocyclic oxygen compounds in the animal body.

An adequate yet brief review of so many topics clearly cannot be achieved, but the volume may be warmly recommended to organic chemists: it is excellently printed and produced apart from two faults, first, the table of contents appears at the end of the volume in place of a real index, and secondly, the fact that publication of the volume lags three years behind the colloquium itself.

The appearance of one more volume in the series on "The Chemistry of Heterocyclic Compounds" is warmly welcome, for the completion of the series will give organic chemists a detailed and authoritative account of almost every aspect of the subject. The six-membered cyclic triazines and tetrazines probably represent to many chemists one of the less-familiar sections of heterocyclic chemistry. Much of our knowledge is at present based on inadequate evidence, and the authors make the reservation that the "structures assigned to many of these compounds rest only upon their modes of formation and upon elemental analyses. We have accepted these structures without comment, except where equally likely or more plausible structures may be written".

Chemists are greatly indebted to the authors for this well-balanced and very thorough account of their subject. The greater part of the volume is naturally devoted to the 1 : 2 : 3-triazines, the 1 : 2 : 4-triazines and the 1 : 2 : 3 : 4-tetrazines, and the classification of the members of each of these groups is particularly clear. It is noteworthy that the final class—that of the pentazines—contains only one member, with considerable evidence that it is actually a tetrazole.

The contents of the volume cover material published up to 1950, with the inclusion of a few later references of particular interest.

The arrangement and the printing of the contents are very attractive, and considerably enhance the ease and pleasure with which the book can be read. It forms a valuable addition to the series.

F. G. Mann

The Story of Evolution

By Sir Julian Huxley. Pp. 72. (London: Rathbone Books, 1958.) 17*s.* 6*d.*

A SURVEY taken by the Audience Research Department of the B.B.C. showed that, despite developments in the teaching of biology in secondary schools, few members of the general public have much accurate knowledge of the theories of evolution and the facts upon which they are based. What better choice, therefore, than Sir Julian Huxley to tell how living things have evolved in a book meant for the layman and designed to combine education with entertainment. Evidence to support the theories of evolution is succeeded by an account of the mechanics of the process, the contemporary attitude to evolution and how it is likely to proceed. All this is explained in language which, though not difficult for the non-specialist to follow, lacks nothing of the precision contained in the author's standard and well-known work, "Evolution: The Modern Synthesis". The text forms a small part of the whole, however, and mainly serves to link the rich collection of attractively coloured diagrams, paintings and photographs; all the diagrams have been prepared by the Isotype Institute.

The photograph of T. H. Huxley on the cover-plate may serve to remind readers of the part played by Sir Julian's grandfather as Darwin's bull-dog three generations ago; this attractive volume will support the grandson's claim in the present generation.

T. H. HAWKINS

Lubrication Science and Technology

Vol. 1, No. 1. Edited by John Boyd. (Publication of the American Society of Lubrication Engineers. ASLE Transactions, Vol. 1, No. 1.) Pp. vii+231. (London and New York: Pergamon Press, 1958.) 105*s.* net.

DURING the past dozen years or more the American Society of Lubrication Engineers has been publishing in its monthly journal, *Lubrication Engineering*, a wide range of articles on lubrication problems. In addition, the Society has held annual conferences at which many papers have been presented, and has participated in conventions on lubrication organized by other scientific and technical bodies. Because of these activities and the increasing interest being shown in the field of lubrication, the Society has decided to publish on a semi-annual basis a volume of transactions to be known as "Lubrication Science and Technology". The first volume, under the editorship of John Boyd, has now appeared and contains nearly thirty articles.

The contents cover an extensive range of interests and appear to fall into three main groups. In the first group are articles dealing with the practical choice of metals and lubricants for specific applications, factors governing fatigue in bearings and gears, the phenomenological wear-behaviour of piston rings and the practical behaviour of solid lubricants. In the second group are papers on the more fundamental level dealing with the mechanism of boundary lubrication and the dependence of wear on specific interfacial interactions: in this group are two papers which attempt to approach metal-machining operations in terms of a rate-process mechanism. The third group deals with design problems and includes papers on finite journal bearings, hydrostatic bearings and the elasto-hydrodynamic behaviour of slider-bearings. There is also a short impressive paper on the design of thrust bearings which can operate up to loads of 2,000 tons or more. Two papers which reflect the atomic age deal with radiation damage in lubricants and lubrication by liquid metals.

It is clear from the selection of the papers included that a serious attempt has been made to balance technological and fundamental work. Nevertheless, the overall impression is that this volume reflects the Society's intention, clearly enunciated in the preface, namely, "to encourage the pursuit and dissemination of the basic technical information necessary for solving industry's problems" in the field of lubrication.

D. TABOR

Planetary Co-ordinates for the Years 1960–1980

Referred to the Equinox of 1950·0. Prepared by H.M. Nautical Almanac Office. Pp. xix+160. (London: H.M. Stationery Office, 1958.) 30*s.* net.

THIS volume is very much more than the ephemeral publication which its title might suggest. It is a continuation of two earlier publications which cover the years 1800–1940 and 1940–60 and extends in convenient form for a further twenty years the data which are needed in the computation of the positions of the smaller bodies in the solar system. The tabular matter is preceded by an introduction in which is given a detailed comparison of the methods for computing the perturbations of comets and minor planets, and at the end of the volume there is a collection of all the formulæ which are needed in eight different methods. These methods are scattered widely in the literature, and most of the text-books which discuss any of the methods do so from an academic point of view. Astronomers and students beginning the study of orbit computation have often felt the need for a more practical approach to the subject as a supplement to theoretical studies, and they cannot do better than master the contents of the descriptive pages of this volume. As a Government publication no names appear on the title page, but from the preface we learn that the authors were Dr. J. G. Porter, Dr. G. A. Wilkins and Mr. M. P. Candy, and we express to them our compliments on their excellent work.

R. H. GARSTANG

Aggression

By Dr. John Paul Scott. (The Scientist's Library—Biology and Medicine.) Pp. xi+149. (Chicago: University of Chicago Press; London: Cambridge University Press, 1958.) 28*s.* net.

THIS book claims to give "a concise account of scientific knowledge about aggressive behaviour in modern society—its causes, control and consequences". If this is what the reader expects, he will be rather disappointed. He will find two chapters which are reasonably documented. One discusses the physiology of aggression and surveys briefly some of the relevant work of Cannon, Bard, Ranson, Hess, Masserman, and Gellhorn. The other deals with hereditary influences, chiefly sex, size and breed differences in a number of species. The chapters concerned with psychological and social factors fall short of what might have been achieved on the basis of existing literature. In particular, the treatment of developmental, psychiatric, and anthropological aspects of aggression is far from adequate.

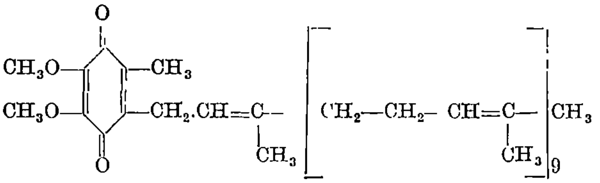
The author states that his primary aim is "to take the important results from current animal research and relate or contrast them with the facts of human behaviour". He has been more successful, however, in reporting the results of animal studies than in giving a convincing account of their bearing on the "facts of human behaviour".

J. COHEN

UBIQUINONE

By Prof. R. A. MORTON, F.R.S.
Department of Biochemistry, University of Liverpool

UBIQUINONE is a new substance of considerable biological interest which possesses the structure:



(I)

It would perhaps be more correct to say that this is the formula for the first of the ubiquinones, as there is already evidence of a plurality of compounds differing only in respect of the long side-chain.

Research on this compound has an interesting and perhaps instructive history. In 1950 G. N. Festenstein[1] obtained from the material lining the horse's gut a substance with an absorption peak at 272 mμ, *E*(1 per cent, 1 cm.) 195, an inflexion at 330 mμ, *E*(1 per cent, 1 cm.) 14 and a weak band at 400 mμ, *E*(1 per cent, 1 cm.) 8. This substance was labile to alkali but could be isolated either from tissue or from its unsaponifiable fraction. The work arose out of earlier investigations at Liverpool on intestinal tissue. It had been found: (*a*) that many species of fish contained large amounts of vitamin A in the intestinal epithelia and in the pyloric cæca; (*b*) that carotene could be converted to vitamin A in the absorptive part of the animal gut; and (*c*) that cholesterol could be dehydrogenated in the gut wall to form provitamin D. Festenstein's study revealed the presence of small amounts of intermediates between carotene and vitamin A as well as the existence of the new 272-mμ substance.

The yield from horse intestine was small, and J. C. Cain[2] began a systematic study of the minor constituents of unsaponifiable matter in liver in the hope of isolating enough of the 272 mμ substance to identify it. Large amounts of liver tissue (horse, ox, sheep) were worked up and the presence of the new substance in liver was established. Liver was not, however, the best raw material to have chosen, although it was natural for this mistake to be made in a laboratory much concerned with vitamin A. Horse liver and ox liver contain substantial amounts of carotenoids as well as of vitamin A, and these substances give rise to artefacts on prolonged processing. In the course of the chromatographic separations, cholest-3 : 5-dien-7-one accumulated in some fractions, and as the ultra-violet absorption spectra of this compound and the new substance are very similar near 270 mμ, it was not always possible to distinguish the two compounds.

Meanwhile, J. S. Lowe[3] and F. W. Heaton[4-6], in an attempt to throw light on the systemic mode of action of vitamin A, had been comparing the unsaponifiable matter, obtained from the livers of rats deficient in vitamin A, with corresponding fractions from the livers of control rats receiving small doses of vitamin A. Similar studies were made on other organs and tissues[7], and a standardized chromatographic procedure facilitated separations. The most interesting fractions were designated SA and SC, the former being the 272 mμ substance. The amounts of both substances SA and SC were greater in the livers of rats deficient in vitamin A than in those of the control animals, but there was little difference in the other organs. The changes in SA- and SC-content of rat liver did not appear in the livers of fowls or guinea pigs deficient in vitamin A. This finding reduced the likelihood that changes in substances SA and SC were direct consequences of the deficiency state. The absence of vitamin A, however, made it technically easier to isolate rich concentrates of substance SA.

Heaton and Lowe[4] obtained enough of substance SA from rat liver for preliminary characterization. A preparation showing *E*(1 per cent, 1 cm.) 272 mμ, 174 and $\lambda_{\text{min.}}$ 234 mμ (*E*(1 per cent, 1 cm.) 36·7) was examined in an infra-red spectrometer and was analysed for carbon and hydrogen. The molecular weight was determined by the Rast method, using both camphor and exaltone as solvents. The results agreed (430 and 433) and seemed trustworthy. It is now known that this was a good preparation and that the analyses were satisfactory, but the molecular weights were almost exactly half the true value. This failure of the Rast method led the whole investigation astray for a time.

The chromophoric properties of substance SA were matched very closely indeed by those of a type of ene-dione steroid structure occurring in cholest-8 : 9-en-7 : 11-dione[4,8]. The analyses and molecular weight made it necessary to explore the possibility that SA was a polycyclic substance of steroid nature. Attempted dehydrogenation (Wohl–Ziegler method and also palladized charcoal) gave no evidence of a polycyclic ring system. G. M. Wilson[9] prepared and examined a number of steroids and related substances containing the 8 : 9-en-7 : 11-dione grouping and showed that they were quite distinct from SA.

It now became clear that substance SA was a normal constituent of many animal tissues. N. F. Cunningham[10] had determined the SA-content of liver, and J. Vernon[10,11] the SA-content of kidney in many species. L. Mervyn[12,13] had found substance SA in human blood, heart and kidney, and also in a fœtus. Miss N. Fahmy[14] had found substance SA in the spleen and pancreas of various species, including man. In the course of a study of yeast unsaponifiable matter a substance, showing the SA spectrum ($\lambda_{\text{max.}}$ 272 mμ, *E*(1 per cent, 1 cm.) 167 in cyclohexane) and other properties, had been isolated (but not crystallized) by Heaton, Lowe and Morton[15]. F. W. Hemming and J. F. Pennock[16] had meanwhile observed that SA was mainly to be found in the mitochondrial fractions of liver and kidney tissue.

Wilson[9] prepared several batches of SA fractions from pig liver, and after rechromatography he was able for the first time to crystallize the compound. Pig liver was chosen because it is normally almost free from carotenoids and is not rich in vitamin A. When the crystalline material was analysed the results agreed well with the earlier figures, but the Rast molecular weights were disconcertingly variable and higher. These values might have been due to partial dimerization, but the crucial importance of the molecular weight made it necessary to use other methods. The Barger method of isothermal distillation led to a molecular weight of 869 (chloroform as solvent) or 995 (acetone as solvent). Cryoscopic determinations using cyclohexane as solvent led to values from 890 to 1,000 (Hemming and Pennock).

SA was readily reduced by zinc and acetic acid to give a compound showing $\lambda_{max.}$ 291 mμ and E(1 per cent, 1 cm.) 52 (in cyclohexane). The infra-red absorption spectrum showed that the carbonyl bands of substance SA had been replaced by hydroxyl bands. The reduced form was readily re-oxidized to SA by shaking with alcoholic ferric chloride, but it formed a stable acetate. The oxidation-reduction potential of the system SA – reduced SA was found to be $E_0 = 0{\cdot}542$ volt (Wilson). Perbenzoic acid titration indicated 7·5 double bonds on a basis of a molecular weight of 642, or 10 double bonds on the basis of a molecular weight of 860. The low value of E(1 per cent, 1 cm.) for the absorption of reduced SA favoured a high molecular weight. W. M. F. Leat and J. F. Pennock studied the catalytic hydrogenation of SA and recorded an uptake of hydrogen consistent with 8 or 11 double bonds, depending on whether the molecular weight was taken to be 642 or 856. The fully hydrogenated compound was readily oxidized by ferric chloride and the absorption spectrum of SA reappeared almost quantitatively. The new product, however, took up only a small proportion of hydrogen. The whole operation was repeated on a larger scale, and it was found that this proportion was 1/11 that shown by substance SA itself. The molecular weight was thereby finally fixed at about 860 by an indirect method[17].

The behaviour of substance SA was thus consistent with a quinone–hydroquinone system as the chromophoric grouping, with a side-chain transparent to ultra-violet rays and containing 10 unconjugated double bonds. The largest fully characterized molecule of this type was until recently squalene, $C_{30}H_{50}$, with 6 unconjugated double bonds, although many years ago Channon[18] isolated a compound $C_{45}H_{76}$ from liver. Dimter[18] found this hydrocarbon, which he called hepene, in adult mammalian liver but not in fœtal liver, and confirmed the formula $C_{45}H_{76}$. Vitamin K_2 has been hitherto accepted as 2-methyl-3-farneso-farnesyl-1 : 4-naphthoquinone, but it has recently been found (Isler *et al.*[19]) that the main vitamin K-active substance of bacteria has a C_{35} side-chain instead of a C_{30} side-chain.

The possibility that substance SA was related to vitamin K was rejected: (*a*) because of the absence of the four narrow absorption bands in the region 240–280 mμ; (*b*) because the value of 0·542 volt for E_0 was too high; and (*c*) because dehydrogenation did not give a naphthalene spectrum. This meant that substance SA was probably a benzoquinone derivative, but only half the oxygen content could be accounted for in this way. Alkoxy determinations were made (7·07 per cent), and on the basis of a molecular weight of 860 two methoxyl groups became probable. Their presence would also contribute to the lowering of the oxidation-reduction potential of *p*-benzoquinone from 0·715 to 0·542 volt.

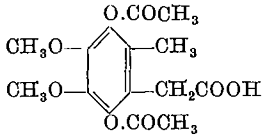
Towards the end of 1956, when the perbenzoic acid titration had indicated that substance SA contained a 'polyisoprenoid' system, the help of Dr. O. Isler, of Hoffmann–La Roche at Basle, was sought because of his great experience in the synthesis of such groupings. It was also felt that the scale of preparation of substance SA would have to be increased beyond the capacity of a university laboratory. Actually, J. Y. F. Paterson, Hemming and Pennock succeeded in obtaining 3 gm. of crystalline SA after considerable effort and expenditure on solvent, and Dr. U. Gloor, of Hoffmann–La Roche at Basle, obtained some 37 gm. by following on a fairly large-scale plant the procedures worked out at Liverpool. Dr. O. Schindler, of the University of Basle, undertook further structural investigations preparatory to projected synthetic work.

In 1957 (July 9) Dr. R. L. Lester, of the Institute of Enzyme Research at the University of Wisconsin, sent to Liverpool a copy of a note[20] on the isolation of a suspected quinone (*Q*275) from beef heart mitochondria. The covering letter stated "after this note was submitted we became aware of the interesting work of your group concerning the characterization of an unsaponifiable lipid material with $\lambda_{max.}$ 272 mμ (*Biochem. J.*, 59, 558; 1955). The ultra-violet and visible absorption of the material we have isolated corresponds very closely to your material. Since on reduction with potassium borohydride we find considerable absorption remaining in the 290 mμ region we thought that this might indicate a quinone–hydroquinone reaction. We would be happy to have your comments in this regard". In reply (July 12) a very full account of the results obtained at Liverpool was sent, including carbon and hydrogen analyses, determinations of molecular weight, infra-red and ultra-violet spectra, oxidation-reduction potential, perbenzoic acid titrations, etc. Mention was made that a steroid structure and many postulated naphthoquinone structures had been ruled out. Dr. Lester's reply (August 29) was most interesting. In acknowledging the letter of July 12 on behalf of Drs. Crane and Hatefi he wrote: "The generous information which was supplied leaves us in no doubt that SA, if not identical with Q275, is indeed a very close brother. The properties and analyses are quite close—even concerning the difficulty in obtaining a reliable molecular weight determination. I notice that several of the formulæ described in the letter contain an alkoxyl group—are your alkoxyl values similar to ours? Is there a possibility that an alkoxyl group is due to the presence of alcohol in the isolation? We plan an ozonolysis of the acetate derivative as a means of getting at the nucleus of the compound. Incidentally, Q275 shows no vitamin K activity in the animal assay". A summary of results was given showing very good agreement with those from Liverpool.

By this time it had clearly become necessary to summarize the Liverpool experience and to find a name for SA or Q275. Accordingly, Morton, Wilson, Lowe and Leat[17] suggested 'ubiquinone', and in their publication made reference to the work of Crane *et al.*[20].

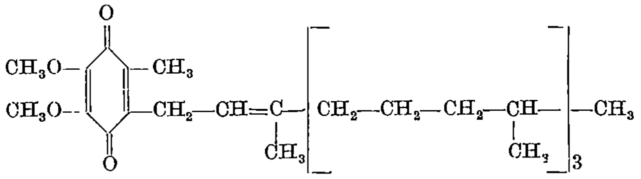
The number of possible structures having been narrowed down, it was decided to search for model substances. The desiderata were a fully substituted quinone (since ubiquinone does not give the Craven test) containing two methoxyl groups. Aurantiogliocladin, 2 : 3-dimethoxy-5 : 6-dimethyl-*p*-benzoquinone had been isolated from a species of *Gliocladium* by Vischer[21] and synthesized unambiguously from *o*-4-xylenol by Baker, McOmie and Miles[22]. A sample of aurantiogliocladin was kindly provided by Prof. W. Baker. This substance was found to show almost exactly the same ultra-violet absorption spectrum as perhydro-ubiquinone. The intensity of absorption E(1 per cent, 1 cm.) 272 mμ = 775 corresponds with a molecular extinction coefficient of 15,190. On the assumption of a molecular weight of 860 for ubiquinone, the E(1 per cent, 1 cm.) value would be 176, which is correct within the uncertainties of the experiment. The behaviour of aurantiogliocladin in ethanolic alkali was exactly similar to that of ubiquinone, although the sequence of chemical changes is not yet clear. Prof. Baker also provided a sample of 3-methoxy-2 : 5-toluquinone, and Dr. Isler and Prof. J. H. Birkinshaw provided samples of toluquinones with two methoxyl groups in the 3 : 4-, 4 : 6- and 3 : 6-positions. The spectra made it extremely probable that ubiquinone was an *o*-dimethoxy compound.

Dr. Gloor had also obtained methoxyl determinations (7·2 and 7·32 per cent), and Dr. Schindler had been able to convert the alkyl iodide obtained into the 3 : 5-dinitrobenzoate ester and had proved by melting point, mixed melting point and paper chromatography that the ester was indeed a methyl ester. This removed any doubt that the alkoxy determinations referred to methoxyl groups. Ubiquinol was obtained ($\lambda_{max.}$ 291 mμ, E(1 per cent, 1 cm.) 50) by reducing ubiquinone by means of hydrogen, using a partially poisoned palladium catalyst, and ubiquinol diacetate was crystallized; melting point, 37° C.; C, 79·5, 79·85 per cent; H, 9·93, 9·96 per cent; $C.CH_3$, 6·54 per cent. (Kuhn–Roth determinations at Liverpool gave similar low results, but this is not unusual for the method.) By ozonolysis of ubiquinone Dr. Schindler obtained acetone, lævulinic acid and a ring compound (II):



(II)

Dr. R. Rüegg had synthesized a compound, (III), which gave the same ring compound:



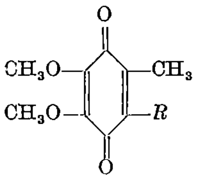
(III)

The dihydroderivative of (III) showed the same infrared absorption peaks as perhydroubiquinone, but the relative intensities were different.

Ubiquinone is in some sense a vitamin for the animal (inasmuch as the synthesis of the benzene ring cannot be effected), but until its biogenesis has been established its status in this respect remains uncertain. N. F. Cunningham[23] showed that guinea pigs deficient in vitamin C were normal in respect of substance SA, as were rats deficient in vitamin D. W. E. J. Phillips (unpublished work) has shown that animals deficient in vitamin K (made so by incorporating sulphadiazine into a diet lacking vitamin K) showed normal ubiquinone content. Mervyn's finding of ubiquinone in a fœtus probably rules out dependence on intestinal micro-organisms. Deprivation of vitamin E did not influence the level of ubiquinone. No diet at present in use for inducing deficiency of known fat-soluble vitamins has so far interfered with ubiquinone contents.

At the Fourth International Congress of Biochemistry held in Vienna in September 1958, Y. Hatefi read, on behalf of the Wisconsin group, a paper dealing with the coenzymic role of Q275 (ubiquinone), and Prof. E. C. Slater[24], of Amsterdam, discussed the biological role of ubiquinone in a survey of the role of tocopherol. In the discussion, M. Tishler, of the organic research group of Messrs. Merck, Sharp and Dohme, gave good evidence[30] for formula (II) for Q275.

The structure of ubiquinone was disclosed at the Sheffield meeting of the Biochemical Society (July 18) by Fahmy *et al.*[25] and quoted by Slater on the basis of the precirculated abstract. With a long chain of unconjugated double bonds it is obvious that neither *cis-trans* isomerism nor partial hydrogenation can be ruled out, any more than side-chains with less than fifty carbon atoms. There may, indeed, be many ubiquinones. Already much interest is being shown in the biochemistry of ubiquinone[26]. The Wisconsin group led by D. E. Green[27] indeed approached the subject through the study of mitochondrial enzyme systems, and because of this they have suggested[28] the designations mitoquinone and co-enzyme Q. In view of the use of Q to designate an enzyme of great importance in carbohydrate biochemistry, the latter suggestion has obvious disadvantages. Moreover, much remains to be discovered concerning the biochemical function of ubiquinone. Although the substance is found in mitochondria, the name 'mitoquinone' is perhaps less happy than ubiquinone with its reminder of widespread occurrence. The term ubiquinone may be used for all substances having the structure:



where R is an unsaturated side-chain. This can be described separately.

The ubiquinone of yeast has been proved by Gloor *et al.*[29] to differ from that of heart tissue, and at Vienna, Tishler also referred to a multiplicity of related compounds. The degree of purity needed for characterizing such compounds is not easily obtained on a small scale.

Detailed proof of the structure of ubiquinone will be given in a forthcoming joint publication by the Liverpool and Basle groups in *Helv. Chim. Acta.*

The work at Liverpool owes much to a grant from the Nuffield Foundation (1954–57) and to the award of scholarships to research students by the Agricultural Research Council and the Medical Research Council. Many colleagues have given valued assistance and advice.

INCH-METRIC CONVERSIONS IN BRITISH STANDARDS

By F. A. GOULD, O.B.E.

British Standards Institution

WHEN legislation was first introduced in the United Kingdom to permit the use of the metric system of units where desired, provision was made to enable those who had to deal with metric measures to convert them into their equivalent values in the British system. A table of equivalent values was included in the Weights and Measures Act, 1878, but it was not until 1898 that a table of equivalents for weights and measures used in trade was prescribed in law (Statutory Rules and Orders No. 411). These equivalents include conversions from metric to British units and vice versa, but their primary purpose was to enable such metric measurements as were encountered in trade to be expressed in the usual, that is to say, the British, system of units. The use of these conversion factors has since extended, partly as the result of increased trade with countries using the metric system and partly as the result of certain industries in Britain using the metric system. To-day many conversions enter into the specifications found in British Standards. "Conversion Factors and Tables" (B.S. 350), which is now undergoing revision, gives a wide range of information regarding conversion factors in general. The concurrent use of both systems of units is recognized by the International Organization for Standardization (ISO), which makes due provision for conversions between British and metric units. The change to the metric system in India has also contributed to the need for publication of authentic conversion factors.

Of the conversion factors in use, those for the conversion of inch and metric sizes are of great importance in trade in countries using the metric system. Such conversions are needed, not only for describing equivalent nominal designations in the two systems but also for the purposes of functional interchangeability between articles made to specifications in either system of measurement. In many cases precise dimensional interchangeability is required. Such precise conversion of inch and metric sizes sometimes necessitates a close examination of the basis of the accuracy of the conversion factor used.

Basis of Conversion

Since the British yard and the metre are defined by reference to the material prototypes called respectively the imperial standard yard and the international prototype metre, the relation between these is a matter for experimental determination. One such determination had been made a few years before the issue of the Order in Council of 1898, and the result was included with the basic equivalents given in the Order. For the purposes of trade, rounded conversion factors were legalized, and the factor 1 inch equals 25·400 mm came into use. This round value was estimated to be correct to within one part in a million. It was afterwards applied to other conversions than those for measures of length occurring in trade, and was used, for example, in the determination of conversions for pressure and stress and other quantities, as required in science and industry.

In the first edition of "Conversion Factors and Tables" (B.S. 350), issued in 1930, the use of the round factor 1 inch equals 25·4 mm was recommended. So far as accuracy was concerned, this simple factor was amply sufficient for most purposes, and only in exceptional cases where fine measurements were involved was there any need to use a more precise conversion.

In two respects, however, it became necessary later to reconsider the appropriateness of using the factor. A further determination of the relationship between the yard and the metre (made in 1922 by the National Physical Laboratory on behalf of the Board of Trade, which has the custody of the imperial standard yard) showed that the round factor 1 inch equals 25·4 mm was then true to within two parts in a million. While confirmatory measurements made in 1932 indicated that any change in the relationship was very small, a further determination in 1947 revealed a progressive shortening of the imperial standard yard.

In the meantime, metric measures were of sufficient importance in American industry to lead to the adoption of a simple factor for converting inch to metric sizes. In 1933, the American Standards Association approved the adoption of the round factor 1 inch equals 25·4 mm for industrial use in its standards. The adoption of the same conversion factor for industrial purposes by Britain and by the United States was of evident advantage to both countries. The factor was sufficiently simple to enable, for example, gear wheels having 127 teeth to be used in machine tools and measuring machines for the direct conversion of inch to metric measures.

Status of Round Factor

The factor 1 inch equals 25·4 mm does not purport to define the inch in either country. In Britain the inch is defined by reference to the imperial standard yard, as prescribed in the Weights and Measures Act, 1878. In the United States the inch is derived from the metre by means of the definitive relationship, 1 yard (US) equals (3600/3937) metre. The difference between the British and the United States inches amounts to four or five parts in a million, the former being the smaller. The round factor 1 inch equals 25·4 mm corresponds to an inch which lies approximately midway between these two inches and can, therefore, be regarded as representing either of them with an accuracy of two (or three parts at most) in a million.

While for most purposes this difference is not of serious consequence, difficulties have arisen in regard to some types of precision engineering products which are made to very fine tolerances. In such cases products found acceptable in the United States might be rejected in Britain, and vice versa. It is significant that greater interchangeability of precision products among the different countries using either system of units is called for by modern conditions of life, apart from the experiences of the Second World War. Moreover, an urge in this direction comes also from International Standards conferences and from the defence requirements of several countries.

Proposals to Re-define the Inch

The fact that the inch is not uniquely defined throughout the world presents an embarrassing problem from national and industrial points of view. The continued use of the imperial standard yard (the legal standard) as the fundamental standard of length in the British system, in view of the evidence of a progressive decrease in its value in terms of the international metre, accentuates the difficulties encountered in reference to fine measurements of length.

About twenty years ago, a proposal to redefine the inch as exactly equal to 25·4 mm, corresponding to 1 yard equals 0·9144 metre, was made in Commonwealth countries and in the United States. This proposal, with a similar one for the pound, was discussed by British and American metrologists during the Second World War and was put forward by the British Commonwealth Scientific Official Conference in 1946. It was also recommended by the Inter-Departmental Committee on Weights and Measures Legislation in 1951. Legislation to give effect to these proposals in Britain has not so far been enacted. In the United States a similar proposal had been made before the Second World War, but had met with opposition from certain engineers and surveyors, including the Coast and Geodetic Survey. Further efforts were made in the years following the Second World War, but the same opposition again prevented legislative action being taken. It is now proposed by the U.S. National Bureau of Standards that an 'international yard', defined as exactly equal to 0·9144 metre, should be established by negotiation with the major English-speaking nations and should be used generally for scientific and industrial purposes. This approach would not require legislation by Congress, and the Coast and Geodetic Survey could continue the use of its present units so long as it is considered desirable.

In Canada the change was effected in 1951 by legislation defining the yard as equal to 0·9144 metre exactly. In Australia, provision for a National Standards Commission, to establish standards for various units of measurement, was made in the Weights and Measures Act of 1948, but no formal pronouncement for the yard or inch has yet been made.

Effects of Proposals on British Standards

It is too early to foresee the outcome of these proposals in Britain and the United States. A general adoption of the proposals for unifying the inch would remove all doubt as to the precise meaning of an inch and would translate, from an approximate to a definitive basis, the factor 1 inch equals 25·4 mm which has hitherto been used so extensively in different countries, and in particular in British and American Standards. All inch and metric conversions of length in British Standards would then be on a true and exact basis.

The British Standards most concerned are "Precise Conversion of Inch and Metric Sizes on Engineering Drawings" (B.S. 2856), and "Conversion Factors and Tables" (B.S. 350). In these Standards, and particularly in the former, the use of the round factor 1 inch equals 25·4 mm for all purposes of conversion may not at present meet all the requirements of accuracy in exceptional cases of high precision, and reference may need to be made to the best conversion from the particular inch (British, United States or Canadian) concerned. This difficulty would be overcome if the conversion factor were definitive, instead of being approximate.

In B.S. 350, the status of the factor 1 inch equals 25·4 mm is of great importance because the unit of length enters into the conversion of many compound units, for example, mechanical units and heat units. In the revision of this standard which is now being made, the slight differences between the British and United States inches (and likewise the pounds avoirdupois) have been dealt with by assuming a common basis for the inch, namely, 1 inch equals 25·4 mm (and also for the pound, namely, 1 lb equals 0·453 592 37 kg exactly). This enables most of the conversion factors between British and metric units to be applicable also to the corresponding United States units, with the exception of those units, chiefly units of capacity, which are markedly different in the two countries. This treatment in B.S. 350 provides a very good compromise for industrial purposes, coupled with its additional applicability to most United States units.

BACTERIOPHAGE RESEARCH

SECOND ROYAUMONT COLLOQUIUM

IN the summer of 1952, André Lwoff, of the Institut Pasteur, organized an International Bacteriophage Colloquium at the Abbaye de Royaumont near Paris, the first reunion of European and American phage workers since the renaissance of the early 1940's of interest in bacterial virus. That meeting was held at a crucial time in phage research; for it had only just been discovered then that the tail of the phage is the organ of attachment, that the deoxyribonucleic acid of the phage is the carrier of its hereditary information, that genetic recombination of the phage can be understood in terms of population genetics, that the prophage of lysogenic bacteria is located on the bacterial chromosome, and that genetic recombination in bacteria is a unidirectional process involving donor and receiver cells. It was, therefore, fortunate that an international group happened to meet to appreciate these novel findings, which permitted old questions to be reformulated at a higher level of sophistication.

An unfortunate change has occurred since that Colloquium, when it was still the rule that all first-rate phage workers were always aware of everything important in their entire field. In the past six years, phage research has experienced such a remarkable development that there remain few, if any, persons who still retain complete mastery of every aspect of knowledge of bacterial viruses. Hence, it was appropriate that a Second International Phage Colloquium should be held at Royaumont during July 28–August 2, attended by sixty workers from Australia, Belgium, Denmark, France, Germany, Great Britain, Italy, Japan, Hungary, Switzerland and the United States. No papers were read (nor lantern slides projected) at this meeting, nor will there be any publication. Instead, each session was devoted to the discussion of a given topic under the leadership of a chairman, after an introductory talk on the subject by a *rapporteur*, according to the following programme:

TOPIC	CHAIRMAN	RAPPORTEUR
Anatomy of the Phage Particle	E. Kellenberger (Switzerland)	S. Brenner (Great Britain)
Metabolism of Infected Bacteria	R. M. Herriott (United States)	E. Volkin (United States)
Synthesis of Phage Constituents	O. Maaløe (Denmark)	G. Streisinger (United States)
Kinetics of Recombination	A. H. Doermann (United States)	C. Bresch (Germany)
The Elementary Recombination Act	C. Levinthal (United States)	R. Edgar (United States)
Genetic Fine Structure	G. S. Stent (United States)	S. Benzer (United States)
Replication	F. H. C. Crick (Great Britain)	F. W. Stahl (United States)
Prophage and Chromosome, Transduction	E. S. Anderson (Great Britain)	J. Lederberg (United States)
Phage Conversion	B. A. D. Stocker (Great Britain)	N. Groman (United States)
Bacteriocines	G. Ivanovics (Hungary)	P. Frédéricq (Belgium)

As is evident from this programme, the discussions ranged over a wide field, and to attempt a synthesis of their outcome would be a formidable task indeed. Hence only a rather fragmentary selection of a few of the more important developments to emerge at these proceedings can be mentioned here.

Refined electron, optical and chemical studies reported by S. Brenner have shown that the tail of the bacteriophage consists of three proteinaceous parts: an outermost, cylindrical sheath, enclosing a hollow cylindrical core to which tail-fibres are attached at the distal end. The tail fibres seem to represent the real adsorption organs of the phage, since isolated tail fibres are fixed specifically to bacteria and contain almost all the serum-blocking power of the phage, in contrast to isolated sheaths and cores which possess neither of these properties. The phage, it seems, has a spring; for the sheath is a contractile organ which shortens and thickens when the tail of the phage makes contact with the host cell surface. The sheath, furthermore, is the site of action of adsorption co-factors and inhibitors, which affect the adsorbability of the phage by their influence on a reversible interaction between tail fibres and sheath. The following picture of the infection process may now be inferred from these facts: after phage and bacterium have collided, the phage tail-fibres flail about until they have made a stereospecific fit with the bacterial receptor sites and have anchored the particle firmly to the host surface. The sheath then contracts and pushes the core through cell wall and membrane, so that the viral deoxyribonucleic acid may pass from the head of the phage through the hole in the core into the interior of the bacterium.

Once in the interior of the infected bacterium, the viral deoxyribonucleic acid fulfils two tasks. It replicates itself several hundred-fold to produce the hereditary substance for the progeny particles and it induces the synthesis of viral protein. Parts of both of these processes can be seen directly in some striking electron micrographs of phage-infected bacteria, obtained by E. Kellenberger by means of novel staining and ultra-thin sectioning techniques developed in his laboratory. These pictures show how, in the course of intracellular phage growth, the bacterial 'nucleoids' disintegrate to give way to a pool of viral deoxyribonucleic acid, and how this pool at later stages (but prior to its encapsulation into morphologically intact, infective virus particles) crystallizes into hexagonal, pre-phage structures, which break up into free deoxyribonucleic acid and protein 'doughnuts' if the cell is lysed prematurely. The phage precursor deoxyribonucleic acid thus exists in at least two different states before its maturation, a fact which must be reckoned with if biochemical and genetic 'pool' estimations are to be correlated with one another. A revolutionary advance in the study of the role of viral deoxyribonucleic acid in viral protein synthesis was reported by G. Brown, who appears to have succeeded in inducing *in vitro* the formation of small but significant amounts of phage tail antigens by addition of purified phage deoxyribonucleic acid to preparations of disrupted bacterial cells. Brown has already carried out extensive control experiments to establish the reality of the effects produced in this system, which, if confirmed and developed further, bids fair to become a biochemical philosopher's stone. In the discussion of the replication of deoxyribonucleic acid, F. W. Stahl summarized his and M. Meselson's experiment, in which the density of the deoxyribonucleic acid of bacterial cultures initially labelled with nitrogen-15 was examined after various periods of growth in non-labelled medium (containing only nitrogen-14). Meselson and Stahl have shown by means of this procedure that the replication of bacterial deoxyribonucleic acid follows a semi-conservative course. That is to say, exactly as envisaged by J. D. Watson and F. H. C. Crick, the two complementary polynucleotide strands of the deoxyribonucleic acid macromolecule appear to separate from each other for the replication act and join up with single, *de novo* polynucleotide chains to form two replica molecules, each containing one old and one new strand. The capital importance of this convincing experimental confirmation of the Watson–Crick proposal is obvious. It is hoped that one may know soon whether these results can also be extended to the replication of the phage deoxyribonucleic acid.

The work of many phage geneticists in recent years has indicated that genetic recombination is a process which must be intimately associated with the replication of the hereditary material, namely, deoxyribonucleic acid. It is therefore of great interest that C. Bresch presented a new analysis of the population dynamics of genetic recombination in phage, elaborated independently by himself and by F. W. Stahl and C. Steinberg. This treatment represents a generalization of the Visconti–Delbrück theory, not only in that the nature of the elementary recombination act is not presupposed but also in that the pairwise mating-event of the earlier theory is replaced by a 'co-operation' in which the number of participating particles may be greater than two. A generalization of this sort had become necessary for two reasons: first, studies by Bresch and others have revealed a number of facts which do not agree with the Visconti–Delbrück assumption that genetic exchange in phage occurs by breakage and reunion of homologous parts of mated parental structures. Secondly, Bresch has shown by means of a triparental cross that more than two particles 'co-operate' in genetic exchange, so that mating is *not* pairwise. The implications of the demise of pairwise mating for the understanding of the molecular basis of genetic recombination are not yet clear.

In connexion with this same problem, R. Edgar and A. H. Doermann discussed new experiments pertaining to heterozygotes, those unstable phage genotypes which harbour alleles from parents of a mixed infection and which C. Levinthal first proposed as the transient zygotes formed at every elementary recombination event. Edgar concludes from crosses of several closely linked genetic loci that heterozygotes are indeed formed at the moment of genetic exchange. Furthermore, negative interference (that is to say, multiple exchange between three or more closely linked markers at a frequency greater than that expected from linkage data of two factor crosses) occurs at the time of the segregation of the heterozygote. In order to gain further insight into the genetic structure of the heterozygote, Doermann made crosses involving three closely linked markers and compared the frequency of progeny heterozygotic only for either one of the outside loci with the frequency of progeny heterozygotic only for the inside locus. Contrary to the 'overlap' model of heterozygote structure, now favoured by many phage geneticists, which predicts that phages heterozygotic for only the inside locus should be much less frequent than those heterozygotic for either one of the outside loci, Doermann found that all three types appear in roughly equal yield. Although it is now evident that both negative interference and heterozygosis must hold one of the keys to the understanding of the nature of the elementary recombination act, it is difficult to assess how soon a full comprehension of these phenomena may be at hand.

S. Benzer reported his work on mutation in a single genetic region, or 'cistron', of the bacteriophage. By mapping hundreds of independent mutants produced either spontaneously or under the influence of certain mutagens, he has constructed a mutational spectrum and thus obtained an image of the relative mutability of individual loci within a single gene. The spectrum of spontaneous mutations shows a few 'hot' spots at which mutants recur with high probability and a number of other sites mutating with lower probability. The spectra of mutation induced by 5-bromouracil, 2-amino-purine, or proflavine, all of which raise the overall rate of mutation in the cistron by two orders of magnitude, are very distinctive, in that each of the three mutagens creates its own set of 'hot' spots and mutable sites, totally unlike the set of mutable loci identified either among spontaneous mutants or among mutants induced by the other two mutagens. Bromouracil, amino-purine and proflavine, therefore, are specific mutagens, in the sense that each raises the probability of mutation only at definite genetic loci, rather than causing a generalized mutability of the entire genome. Since concrete notions concerning the mode of action of each of these mutagens can already be formulated in terms of the Watson–Crick structure of deoxyribonucleic acid, mutational spectra promise to bridge the gap between chemistry and genetics.

The past decade saw an ever-growing confluence of phage and bacterial genetics, particularly as non-infective prophage turned out to be an integral part of the bacterial genome in lysogeny, and infective phage a carrier of bacterial heredity in transduction. Recent studies on bacterial recombination, lysogeny and bacteriocines, presented at the Colloquium by J. Lederberg, by R. Frédéricq and by F. Jacob, have revealed, however, that the bacterial fertility factor *F*, the prophage and the colicinogenic factor have certain features in common which set them apart from other, or 'regular' bacterial genes. On the basis of these special properties, F. Jacob and E.-L. Wollman have created a new concept, the 'episome', defined as an exogenous hereditary determinant integrated into the bacterial genome by addition to the chromosome instead of replacement of allelic bacterial loci. Besides its integrated chromosomal state, the episome can also exist in an autonomous state, in which it is replicated independently of the rest of the bacterial genome. The episome promises to bring new order into the dialectics of virus-host genetics.

The second International Phage Colloquium can be considered to have been a great success; not only the participants but also phage workers in general must be grateful to its organizers, A. Lwoff and F. Jacob, and to the Rockefeller Foundation which provided financial support. The week of intimate and informal living within the historic Cistercian monastery founded by St. Louis in the thirteenth century once more promoted understanding, collaboration and personal friendship of a truly international nature. There seems little doubt that this Colloquium, like its predecessor, will have a profound effect on the development of bacteriophage research in coming years.

GUNTHER S. STENT

OBITUARIES

Mr. Cecil Warburton

MR. CECIL WARBURTON died at his home in Grantchester, Cambridge, on October 7 at the age of one hundred and four years and eight months. Although he had lost much of his former physical vigour during the past year or two, he retained to the last his remarkable mental clarity, sense of humour and interest in people and current affairs. Warburton's work as an entomologist and arachnologist was known and respected by several generations of zoologists. His modesty and the charm of his simple and generous personality tended to cloak from those not familiar with his work the solid and enduring value of his scientific achievements.

Cecil Warburton was born on February 6, 1854, at Salford. He was educated at Old Trafford School, Manchester, where he later became second master. He attended classes at Owens College, Manchester, and took a University of London external B.A. degree. He went to Christ's College, Cambridge, in 1886, read for the Natural Sciences Tripos, graduated B.A. in 1889, and took his M.A. degree in 1892.

An early interest in spiders directed his zoological studies towards other Arachnida, and mites and ticks later became his main field of study. His knowledge of general zoology was wide, and he was appointed zoologist to the Royal Agricultural Society in 1893, and from that year until 1940 he wrote an annual report for the Society, dealing largely with economic entomology. At first these reports were addressed from the Department of Zoology, Cambridge, but from 1910 until 1940 they came from the School of Agriculture, where he lectured until his retirement in 1932, thus continuing an association with the teaching of agriculture in the University which had begun as early as 1899–1900 when his name appeared in the list of lecturers for the Board of Agricultural Studies. In 1909 Warburton was the author of Chapters 12–18 of Vol. 4 of the "Cambridge Natural History", which dealt with the Arachnida Embolobranchiata (scorpions, spiders, mites and ticks). This was an important and valuable work, and it provided the background to the fruitful association with G. H. F. Nuttall, then Quick professor at Cambridge, beginning in the Quick Laboratory in 1908, continuing in the Molteno Institute from 1921, and lasting until the death of Nuttall in 1937. It was during this period that his main original contributions were published, dealing with mites and ticks and culminating in the publication, by the Cambridge University Press, of "Ticks; a Monograph of the Ixodoidea", by G. H. F. Nuttall, Cecil Warburton, W. F. Cooper and L. E. Robinson. The first volume was written jointly by G. H. F. Nuttall and Cecil Warburton and comprised: Part 1, "The Argasidae" (1908); Part 2, "Ixodidae" (1911); and Part 3, "The Genus Hæmophysalis" (1915).

These studies were of great value to all workers in the rapidly developing subject of ticks as vectors of diseases of man and domestic animals, and they still remain standard works on ticks. Their preparation and publication resulted in a voluminous correspondence and the submission of collections of ticks for identification from all parts of the world. Replying to innumerable correspondents and identifying and reporting upon specimens occupied much of the time and energy of both Nuttall and Warburton for many years. Warburton continued identifying and reporting upon specimens of ticks until 1936, when he was eighty-two years of age; and there can be few, if any, collections of ticks in any country in the world which are not enriched by numerous specimens bearing on the label the words "identified by C. Warburton".

He had been appointed University demonstrator in medical entomology by the Quick professor in 1911, and he retained this post when the Quick Laboratory moved to the Molteno Institute in 1921. Thereafter, until he retired in 1932, his activities were mainly centred on the Institute, and he lectured on parasitic insects and arachnids, and demonstrated to students taking the courses for the diplomas in public health and tropical medicine and hygiene. He retained a keen interest in the Molteno Institute and those who worked in it to the end, and was an occasional visitor until after his hundredth birthday. Not only did he delight in meeting his old friends there, but also he was always pleased to meet new and younger workers, and all were warmly invited to visit him at his home in Grantchester and play croquet, a game at which he excelled until his sight failed in the last couple of years. He never married. All who knew him will feel they have lost a friend who was warm-hearted, generous and of high integrity both in his private and his scientific life.

P. TATE

Prof. Horace B. Dunnicliff

THE news of the death on October 8 of Prof. H. B. Dunnicliff was received with great regret in India. Dunnicliff had been intimately associated with the growth of chemical education of the country for the past fifty years. He came out in 1908 as professor of chemistry of the M.A.O. College, Aligarh, where he taught chemistry until the First World War. In 1914, his services were placed at the disposal of the Khalsa College, Amritsar. In 1917, he was on deputation to the Munitions Board and was transferred to the Cordite Factory, Aravankadu. There he stayed until 1921 and did some very useful work. He was appointed professor of chemistry, Government College, Lahore, in 1922. On the reorganization of teaching of the Panjab University he was appointed University professor of inorganic chemistry. Here, a good school of chemistry was soon founded with the help of the late Santiswarup Bhatnagar. Bhatnagar was in charge of the teaching of physical chemistry and Dunnicliff looked after inorganic chemistry.

I was in charge of the organic chemistry section when Dunnicliff joined the Panjab University. The success of the Lahore School of Chemistry was largely due to the untiring efforts of Dunnicliff to keep the ship on an even keel in the stormy communal waters of the Panjab. He had a keen sense of justice and fair play, which kept the University teaching departments free from communal politics. He was seconded to the Government of India in 1928 with the view of organizing the Central Customs Analytical Laboratories. On his return to Lahore in 1929, his Laboratory acted as the appellate laboratory for all matters relating to analyses performed by the various customs laboratories of the Indian ports. He was allowed to hold the post of special chemical adviser to the Finance Department of the Government of India in addition to his duties as a professor in the Government College and the University. This was a great strain, but he never grudged the extra burden placed on him. The work in connexion with the Customs Laboratory was not light. I deputized for him for two periods when he was on leave and I can affirm that this work was quite a full-time job. Ultimately his suggestion to have a Central Customs Laboratory at Delhi was adopted, and he finally migrated from Lahore in 1939 as the head of this new Laboratory.

During his tenure as professor in the University of the Panjab, Dunnicliff published a large volume of work in collaboration with his students, which earned for the Panjab University a reputation as an active centre of research work. Many of his pupils now occupy important positions both in India and Pakistan. They are all grateful for the helping hand he lent whenever they met difficulties. His migration to Delhi helped in putting the Central Revenues Chemical Service on a firm footing. During the Second World War I was again associated with him in war work. Owing to the large demand for morphine and codeine, the production at the Ghazipur Opium Factory had to be re-organized. He also designed the present morphine extraction plant at Ghazipur. He had a flair for designing plant and equipment. On his retirement from the Central Board of Revenues Laboratories, he joined the Department of Transport, New Delhi, where he had to design portable producer gas plants for use in lorries and motor-cars in order to minimize the use of petrol.

Dunnicliff presided over the Chemistry Section of the Indian Science Congress in 1934. He was on the Indian Committee of the Royal Institute of Chemistry, and he and the late Prof. Gilbert Fowler did much for the Institute in India.

Dunnicliff was a good singer, and many a pleasant evening was spent by his friends at his home; he was also a proficient amateur actor, and during the summer season he produced many plays at Simla.

Dunnicliff will always be remembered in India as a good Englishman who gave it more than he received from it. Those who knew him recognized him as a giver and not a taker. He lived in India at a critical period of her history. His contribution to the growth of science in India was by no means negligible.

He leaves behind a devoted wife, to whom our sympathy is offered. J. N. RAY

Dr. S. L. Smith, C.B.E.

BY the death of Dr. S. L. Smith on October 27, engineering and in particular shipbuilding research in Britain have lost a prominent figure. Those who had the privilege of working with him will remember him as the most kindly and approachable of colleagues.

Stanley Livingston Smith was born in 1889 and received his technical education at the City and Guilds Engineering College, South Kensington, where he graduated as B.Sc. (London) and Associate of the City and Guilds Institute in 1909. A period of practical training at the Thames Ironworks, Shipbuilding and Engineering Co., Ltd., was followed by an engineering inspectorship with the Crown Agents for the Colonies. After a varied career during the First World War, including secret work for the Royal Society war committee and service as an engineering officer in the marine training section of the R.A.F., he returned to the City and Guilds College under Prof. W. E. Dalby. Awarded the degrees of M.Sc. in 1921 and D.Sc.(Eng.) in 1923 for his work on elastic hysteresis in steels, he was appointed assistant professor in 1926 and reader in mechanical engineering five years later. He represented the Imperial College of Science and Technology on the Surrey County Council and was appointed chief engineering inspector of technical institutions.

Just before the outbreak of war in 1939, he was appointed superintendent of the Engineering Department of the National Physical Laboratory. During the War he was responsible for the very varied war-work of that Department; to mention only three items, he was particularly concerned with the development of apparatus for rendering unexploded bombs harmless, gun design (he was a member of the Gun Design Committee), and (with the late Dr. G. A. Hankins) the building for external ballistic work of an 11-in. square supersonic wind tunnel, which until late in the War was the only supersonic tunnel of reasonable size available to the United Nations.

Despite these preoccupations, Smith found time for probably his most notable personal research, producing with Dr. W. A. Wood four papers on the application of X-ray methods to the study of the deformation and fracture of metals. It is, however, as an administrator of scientific research that he will be best remembered. In 1944, he became the first director of research of the British Shipbuilding Research Association, a post which he still held at his death. Under his leadership the Association has become the central research organization in Britain for the shipbuilding, ship-repairing and marine engineering industry. He organized the work of the Association in an unusual way; no laboratory was set up, but a wide variety of research contracts was placed with universities, other research institutions and industrial firms. Among many papers by Dr. Smith covering this work may be mentioned his Thomas Lowe Gray Lecture to the Institution of Mechanical Engineers in 1952 on ship research, that on the resistance experiments with the old Clyde steamer *Lucy Ashton*, modified for jet propulsion to avoid propeller drag, and recent papers on nuclear propulsion.

Smith was made C.B.E. in 1951. He had been a vice-president of the Institutions of Mechanical Engineers and of Naval Architects, and a member of many technical committees on marine (including nuclear) propulsion, structural steel, corrosion and other subjects, as well as of committees of other research institutions. D. G. SOPWITH

Prof. H. J. Logie

PROF. H. J. LOGIE died on November 8 at the age of thirty-nine. His untimely death came at a period when his research had become very productive, and has been a shock and a great loss to all his colleagues and friends. He received his early education at Benoni High School, went to the University of the Witwatersrand as a student in 1936 and graduated bachelor of science in 1938 with firsts in both mathematics and physics. In 1939 he was awarded first-class honours in physics, and in

1940 he was appointed a junior lecturer in physics. He soon resigned in order to go on active service, and at the age of twenty-four attained the rank of major in the Special Signals Services (Radar) of the Union Defence Force.

Prof. Logie rejoined the University staff in 1946. Despite the very heavy teaching duties which the staff undertook on account of the large number of ex-Servicemen returning to South Africa, he took part in an active research programme in the recording of the Witwatersrand earth tremors. He was awarded the degree of doctor of science in 1949 for a thesis on this work.

In 1950 the staff of the Department of Physics agreed to form a team working together in the field of the physics of the solid state, and Prof. Logie spent a year studying the physics of metals in the University of Birmingham. On his return he started experimental and theoretical research on internal friction in metals and alloys. He was chosen as the first occupant of the newly established chair of experimental physics. On taking up his new appointment, Prof. Logie assumed responsibility for work on the changes of electrical resistivity produced by plastic strain in alloys, and on the electrical properties of counting diamonds.

In addition to teaching and research, Prof. Logie played a large part in other University activities, while outside the University he found time for many scientific and public services.

For the last seven years of his life he suffered from ill-health, but it was characteristic of the man that he spared himself so little as to make this generally forgotten. Friends will remember his lively wit and his warmth as a family man. F. R. N. Nabarro

Prof. F. A. Paneth, F.R.S.

Prof. H. Dingle writes: "The obituary notice of the late Prof. F. A. Paneth in *Nature* of November 8 omits to mention one incident which is at the same time so characteristic of the man and so noteworthy in itself as to justify recalling. On his appointment to the chair of chemistry at the University of Durham, Paneth at once began to interest himself in the local scientific associations, and his attention was captured by the then shadowy figure of Thomas Wright, who first discerned the true character of the Milky Way and whose 'Original Theory of the Universe' (1750) was the source of the idea that inspired Immanuel Kant to write his 'Allgemeine Naturgeschichte und Theorie des Himmels'. With his customary energy and enthusiasm, Paneth brought to light a number of forgotten facts and neglected relics of Wright, discovered that two notices in Allibone's 'Dictionary of English Literature', ostensibly relating to two different persons, in fact referred to the same versatile Thomas Wright, and identified Wright's 'observatory'—a round stone tower which he had caused to be erected at Westerton, near Durham, of which the origin had been completely forgotten; it was known locally as the 'Westerton Folly'. Paneth succeeded in arousing public interest, and in June 1950, the two-hundredth anniversary of the publication of the 'Original Theory of the Universe' was celebrated by public meetings at which, among other events, a collection of Wright memorials was exhibited, a commemorative tablet affixed to the tower was unveiled, and a wreath was laid on Wright's grave. Durham has a special reason to honour Paneth's memory".

NEWS and VIEWS

Physiology at Aberdeen: Prof. E. W. H. Cruickshank

Prof. E. W. H. Cruickshank, who has recently retired from the regius chair of physiology in the University of Aberdeen, from which he graduated, is the living embodiment of the 'wandering Scot'. He graduated in medicine in 1910, and one year later he was in University College, London, with Starling. There he made the significant discovery that, in pancreatectomized dogs, the cardiac muscle, unlike skeletal muscle, stores glycogen. This work, however, was interrupted by the First World War, and it was not until 1919 that, at the invitation of the Rockefeller Foundation, he returned to academic life in the laboratory of Erlanger in St. Louis. He then went to the new Pekin Union Medical College, where he had his first experience of building up a new department from scratch. Yet he found time to continue his study of cardiac metabolism; he also worked on respiration and on general metabolism.

The year 1924 found him back in Britain, in Cambridge. Under the influence of Sir Joseph Barcroft, he showed that the spleen, in the dog at least, acts as a reservoir of blood. In collaboration with Anrep he put on a quantitative basis the coronary blood flow in relation to the activity of the heart. Then Cruickshank went to India as the first professor to build up a Department of Physiology and Biochemistry in the Prince of Wales Medical College at Patna. Two years later an invitation reached him to go to Dalhousie University in Nova Scotia. Here he had seven active and happy years devoted largely to research on metabolism of the heart—an authoritative article from his pen is to be found in Vol. 16 of the *Physiological Reviews*. The final 'call' came in 1935 when Cruickshank succeeded his friend, J. J. R. Macleod, in the chair at Aberdeen. Cardiac metabolism continued to be his main preoccupation, although he was also caught up in the general interest in nutrition and wrote a small book on this subject. In his later years, under the auspices of the World Health Organization, he has had the pleasure of visiting many medical schools in parts of the world where he himself had been a pioneer in establishing physiology as an academic discipline.

Prof. J. Laurence Malcolm

Prof. Malcolm, who has recently succeeded Prof. Cruickshank in the regius chair of physiology in the University of Aberdeen, comes from New Zealand. His first degree was B.Med.Sci. of the University of Otago and he then proceeded to the M.B., Ch.B. in 1938—a proper emphasis on the scientific basis of medicine which unfortunately seems to find less support in Great Britain. While still an undergraduate, Malcolm demonstrated in physiology and studied on rats the goitrogenic action of certain diets. He spent a year as house surgeon in a New Zealand hospital and another year as lecturer in the Department of Bacteriology and Public Health at Otago. In 1941 he became senior lecturer in experimental physiology at Otago, where he remained until 1948. There he came under the stimulating influence of Prof. J. C. Eccles, with the inevitable result that his subsequent work has been in the exacting and modern field of neurophysiology. Neurophysiologists suffer from the same disability as the early microscopists, they must design and build their own equipment.

During 1948–49 Malcolm held an exchange lectureship in St. Thomas's Hospital Medical School, London, and then the readership in physiology with Prof. Huggett at St. Mary's Hospital during 1949–52. The following year he was visiting professor in the New York State University at the invitation of Prof. Chandler Brooks. He then returned to the National Institute for Medical Research in London to the Division of Physiology and Pharmacology. There he used most ingenious and delicate electrophysiological methods to study activities in various parts of the brain: he was even able to study conditioned reflexes in unrestrained animals. The emphasis in the study of the central nervous system is rapidly changing from the anatomical and histological approach to the biochemical and pharmacological. In this new and exciting field Malcolm is using his special techniques to obtain records of the influence of various chemical substances on the brain itself.

Geography in the University of Hull: Prof. H. R. Wilkinson

THE late Prof. Herbert King has been succeeded in the chair of geography in the University of Hull by Mr. H. R. Wilkinson, senior lecturer in geography in the University of Liverpool. Prof. Wilkinson was, like his predecessor, a pupil of Prof. P. M. Roxby in the Liverpool School of Geography, graduating with first-class honours in 1939, and in much of his work reflects that School's traditional interest in human geography. Following six years of war-service, he became senior geography master at Bootle Grammar School. He was appointed by Prof. H. C. Darby to the staff of the Department of Geography at Liverpool in 1947, where, following Prof. Wilfred Smith's sudden death in 1955, he was acting head of the Department for four terms. Prof. Wilkinson's special interests have lain in the fields of human geography and cartography, and he has much first-hand experience of Yugoslavia and adjacent areas of central and south-eastern Europe. His published works include "A Geography of Merseyside" (1948), "Maps and Politics: a Study of the Ethnographic Cartography of Macedonia" (1951), "Maps and Diagrams: their Compilation and Production" (with F. J. Monkhouse, 1952), and numerous papers in geographical and other journals. He was an assistant editor of "A Scientific Survey of Merseyside", the handbook prepared for the Liverpool meeting of the British Association for the Advancement of Science in 1953.

Prof. Wilkinson has served as a member of the Council of the Institute of British Geographers and was a member of the British delegation to the International Geographical Congress held in Washington, D.C., in 1952. He has lectured in Austria and Yugoslavia under the auspices of the British Council. To the growing Department of Geography at Hull he brings a varied experience and a wide range of interests in the subject.

The Inter-University Council for Higher Education Overseas

AT the end of February, Mr. S. J. Worsley will complete his term of office as secretary of the Inter-University Council for Higher Education Overseas. Mr. I. C. M. Maxwell, assistant secretary of the Council since September 23, 1952, will succeed Mr. Worsley. Mr. Maxwell was formerly secretary of the University of London Senate Committee on Higher Education in the Colonies, a body responsible for the development and detailed working of the special relationship of the University of London and certain university colleges overseas. He has, therefore, had considerable experience of higher education in the Colonies and is well-known to members of the staffs of the universities and university colleges with which the Inter-University Council is associated.

Soviet International Press Censorship

STRONG criticism of, and protest against, Soviet censorship of science reporters, especially British and American, have recently been made, according to Mr. Victor Cohn, science editor of the *Minneapolis Tribune*. This was particularly evident in connexion with the International Geophysical Year meeting in Moscow during July–August. Mr. Cohn states that Western correspondents had to file their reports in triplicate at the Central Telegraphic Agency in Moscow; these were censored and then returned to the correspondents "15 minutes or two hours or six hours or 24 hours later, or never". Mr. Cohn has given some examples of undesirable censorship exercised by the Soviet authority.

A group of correspondents wrote letters of protest to Prof. Sydney Chapman, president of the Comité Spécial de l'Année Géophysique Internationale. In one letter it was claimed that "in areas where the public of our nations is concerned, there can be no freedom of enquiry or scientific reporting unless there is also freedom to communicate with the public. It would seem intolerable to hold great scientific meetings in a place where their results cannot be communicated to the people who must support science in our countries". On August 5, Prof. Chapman replied: "It is the view of the C.S.A.G.I. bureau that the press should be able to transmit to the public the views of the participating I.G.Y. committee on purely scientific matters". The newspaper correspondents' protest seems justified, and Prof. Chapman's guarded reply encouraging. It is, to say the least of it, very frustrating when a correspondent cannot be sure that his report of a scientific meeting will be cabled, even after it has been held several hours. This form of press censorship, especially where international conferences and the like are concerned, is much to be deplored.

Science and History

"THERE is within you", said Hobbes, "some special cause of intenebration which you should do well to look to"; and Prof. Douglas McKie in his inaugural lecture delivered at University College, London ("Science and History." Pp. 17. London: H. K. Lewis and Co., Ltd., 1958. 2*s*. 6*d*. net), on May 22 has done us a service. The Department over which he has been called to preside was founded after the First World War as a virtual by-product of discussions centring around an institution for a diploma in journalism. After even further consideration a committee was appointed which recommended that the history of science should be a post-graduate discipline including the study of what was at first method of science but has now become the philosophy of science. Instituted in 1924, it has now some sixty students, and its staff, of which Prof. McKie has been one of the outstanding ornaments, has made a name by careful and scholarly research. In these days as scientific journals increase at the rate of more than a thousand a year, synoptic views need more than ever to be authoritative. Prof. McKie's plea that the history of science should be recognized as a branch of history has already been tried by Dr. J. B. Conant, and University College, London, is trying, too. Looking further, he sees the expansion of this field in the history of technology reaching into the history of medicine. Prof. McKie's modesty makes his inaugural address pleasant reading ; one only regrets that it does not include a little autobiography. He, of all men, should be encouraged to tell us of his own writings and work.

Cotton in the Prehistoric Southwestern United States

THE textiles, old or new, of particular areas have formed the subject of a number of reports published in recent years, which have an interest by no means limited to the areas with which they deal. The late Prof. Lila O'Neale's "Textiles of Highland Guatemala" was a notable example dealing with modern weaving, and a recent report (*Trans. Amer. Phil. Soc.*, N.S., 47, Part 3 : The Cultivation and Weaving of Cotton in the Prehistoric Southwestern United States. By Kate Kent. Pp. ii+457–734. 4 dollars), which is concerned mainly with ancient examples, should command an equally wide interest, not only among textile specialists but also among those who are interested in New World archæology. The work has entailed widespread research among museum collections, as well as painstaking study of individual examples, many of them in poor condition. A great deal of this report naturally consists of descriptions of specimens, but the admirable drawings make it easy to follow the processes and to pick out what is of general interest. The bulk of the material available dates from between A.D. 1000 and 1400, but evidence is given for the use of the loom in the area at least as far back as A.D. 700. It may be remarked that it was far older in some other parts of America, and it will be surprising if it does not eventually prove to have reached the south-west of the United States at an earlier date. The account is not limited to loom-woven fabrics, and it includes such processes as twining, besides netting and other single-element techniques. It was found possible to distinguish the products of several sub-areas in the region.

Of particular interest are suggestions as to how and when various processes were introduced from Mexico from a possible ultimate source in Peru. Brief comparisons are made between looms and processes popular in Peru and the south-west of the United States ; twills, for example, are common in the latter and rare in Peru, where warp floats enjoyed a vogue which was lacking farther north. The wide loom, horizontal or vertical, with fixed beams, was largely used alongside the belt loom in the south-west of the United States, whereas the belt loom predominated farther south, and the evidence for the use of a stationary loom in ancient Peru is still unsatisfactory. The Peruvians always had a taste for finger weaves, whereas there was a greater dependence on loom processes in the south-west of the United States. Observations of this sort direct attention to the desirability of a synthetic study of weaving in different parts of ancient America, a work which would be of great interest and value. This report would form one of its foundations.

Silver Jubilee of *Polarforschung*

THE Archiv für Polarforschung at Kiel has recently published two special issues of its journal, *Polarforschung*: one to celebrate the journal's twenty-fifth anniversary, and the other in memory of Alfred Wegener. Apart from special emphasis in the second on the German Greenland Expedition of 1930–31, these two issues follow the pattern of their predecessors. There are short articles on a wide variety of subjects ; but scientific results of expeditions are not normally to be found here. The jubilee issue, for example, includes a summary of the weather at Vorkuta by an ex-prisoner there, a discussion of dreams during the polar night by a doctor, a survey of volcanic activity in Iceland since 1700, and many more notes further exemplifying this diversity. The somewhat austere layout and type face, together with the absence of diagrams or illustrations, should not deter the careful reader, who will find information of interest and value not available elsewhere. Polar specialists will be sorry to hear that Dr. Max Grotewahl, the founder and organizer of the Archiv für Polarforschung, died on September 6, shortly after the appearance of these two issues.

National Museum, Bloemfontein

THE annual report of the National Museum at Bloemfontein for the year ended March 31, 1958, (pp. 22. Bloemfontein : National Museum, 1958) records the completion of ten new displays, including dioramas of vultures, pan-life (birds), *Uranocentrodon* (fossil amphibian) and *Aulacocephalodon* (fossil reptile). Several minor building extensions have been undertaken, although no start has yet been made on the two new wings for the Museum. Four members of the staff are studying at and writing theses for the Department of Physical Anthropology in the University of the Orange Free State at Bloemfontein, and various grants-in-aid enabled the Museum to undertake large-scale excavations at the Matjes River rock shelter.

Uptake and Translocation of Radioactive Phosphorus in Plants

G. N. THORNE (*Annals of Botany*, N.S., 32, 381 ; 1958) has investigated and discussed the factors which affect the uptake of radioactive phosphorus by leaves and its translocation in the plant. The rate of uptake of phosphorus-32 from solutions of labelled sodium dihydrogen phosphate sprayed on to one leaf of swedes (*Brassica napus*) or french beans (*Phaseolus vulgaris*) was rapid during the first few hours and fell to zero after four days. Phosphorus-32 was detected in the root after 3 hr. and continued to move out of the treated leaf for at least six days after application. A larger fraction of the applied phosphorus-32 was absorbed from repeated than from a single spraying. Swedes absorbed more phosphorus-32 from a single application to the lower surface than to the upper surface of the leaf. Doubling the concentration of the spray caused a small increase in the percentage of applied phosphorus-32 that was absorbed. Absorption by french bean leaves decreased slightly when the area sprayed with a constant amount of phosphorus-32 was doubled, and decreased with increasing age of leaf. Increasing the supply of phosphorus to the roots of swedes affected neither the initial rate nor the total uptake of phosphorus-32 by the leaves, but decreased the quantity of radiophosphorus that was translocated out of the treated leaf. Increasing the relative humidity of the air around the plants also increased uptake of phosphorus-32. Shading usually decreased uptake and always decreased translocation. Re-wetting the leaf to which the radiophosphorus had been applied, with water or sucrose solution, had variable effects.

Establishment of *Pythium* in Soils

R. BARTON has reported that, whereas species of *Pythium* can be isolated from cultivated soils by using susceptible host seedlings as bait, they could not be isolated from woodland, non-cultivated or very acid soils (*Trans. Brit. Mycol. Soc.*, 41, 207 ; 1958). The behaviour of inocula of *Pythium mamillatum* in a cultivated (native) soil, and in a woodland (alien) soil was assessed by means of the host test described. Maize meal added to the cultivated soil became colonized by *P. mamillatum* after only two days, indicating that, under these conditions, the parasite behaves as a saprophytic 'sugar fungus'. In the alien woodland soil, *P. mamillatum* did not colonize maize meal. After neutralization of this acid soil with lime, however, the fungus rapidly utilized the material. The parasite could not be grown in culture at the low *p*H value of the alien soil. The behaviour of vegetative hyphæ of *P. mamillatum* in these contrasting soils was studied by the glass-fibre tape technique. In native, cultivated soil, oospores and resting sporangia were formed abundantly, whereas in alien woodland soil these bodies were not produced. Thus, the inability of *Pythium* hyphæ to produce a resting phase may prevent long-term survival of the parasite in alien soils. This effect was shown to be due to low *p*H value of the soil, which may directly limit the normal life-cycle of *Pythium* in acid woodland soils.

Researches on Tropical Vegetation

THE scientific study of the rich and varied floras of tropical regions not only brings its own reward but also is of very real practical importance. The wise utilization of forested tropical lands is not merely something to be desired : it has been recognized as a problem of considerable urgency for many years, especially in regions of increasing population. A Unesco publication on humid tropics research entitled "Study of Tropical Vegetation" (written in both English and French. Pp. 226. H.M.S.O., 1958. 30*s*.), records the proceedings of a symposium held in Kandy, Ceylon, in 1956, and prepares the way for further investigations. Tropical forests, growing on soils of varying fertility, are the raw materials of agriculture, whether this be pursued piecemeal by small farmers or extensively by large plantation companies. Swamp and rain forests, though still of vast dimensions in some regions, are certainly not unlimited ; and those on soils of fair to good inherent fertility tend to become a shrinking asset, especially in areas which offer easy or reasonable accessibility. Where this is so, and in conjunction with a rapidly increasing population, the problems of adequate agricultural production become progressively more acute ; and research, combined with appropriate practical action, is seen to be essential. In the present report, some twenty-six technical papers contributed by specialists from thirteen countries give important indications as to what some of the basic problems are and how they may be tackled. In general, the coverage is what might be expected : tropical vegetation, in its many aspects, is described, mapped, illustrated and discussed, especially from the ecological point of view, and the relevant environmental factors analysed. The need for conservation under official auspices and for further study are strongly emphasized. The representative regional surveys and illustrations are specially attractive and valuable features of this volume.

Cocoa Conference 1957

UNDER the above title the Cocoa, Chocolate and Confectionery Alliance (11 Green Street, London, W.1) has published a comprehensive report (pp. xiv+326+35 plates. London : 1958. 63*s*.) giving the full texts of the papers presented at the international conference sponsored by the Alliance and held in London during September 10–12, 1957. The papers—nearly forty in number—are arranged under general headings corresponding to the sessions of the conference : commercial background ; developments in new cocoa-growing areas, planting materials and methods ; disease and pest control ; chemistry of cocoa fermentation ; preparation and quality ; and the cocoa tree in its environment. These titles show the scope of the conference, which brought together 282 delegates ranging from scientific workers in agriculture and food technology to representatives of industry and of government agencies. The majority of the participants were from different parts of the British Commonwealth, and two West African Governments—Ghana and Western Nigeria—were represented for the first time by Ministers. Delegates from different European countries and the United States were also present. This wide representation gave the conference its unique character. The report shows the efforts that have been, and are being, made by scientific workers in the laboratory and in the field to promote a branch of agriculture which is of vital importance to the economic stability of several Commonwealth—as well as other—territories overseas. The report will therefore be of value both to those actively concerned with the cocoa and allied industries and also to economists, agricultural scientists and others who are interested in the problems of the developing countries in Africa and elsewhere. Both these groups of readers will accept the report as an essential source book.

The Ciba Fellowship Trust

THE Ciba Fellowship Trust has been founded by Ciba Clayton, Ltd., Ciba Laboratories, Ltd., Ciba (A.R.L.), Ltd., and the Clayton Aniline Co., Ltd., for the purpose of improving and increasing the interchange of ideas between scientists in the United Kingdom and on the Continent. The trustees are Sir Arthur Vere Harvey, Lord Hives, and Sir Alexander Todd. The fellowships will be awarded by an advisory panel, the members of which are Sir Arthur Vere Harvey (chairman), Prof. A. J. Birch (University of Manchester), Prof. W. Bradley (University of Leeds), Dr. A. Brunner (Ciba, Ltd., Basle), Dr. E. Brunner (Clayton Aniline Co., Ltd., Manchester), Prof. D. H. Everett (University of Bristol), Prof. D. M. Newitt (Imperial College of Science and Technology, London), Dr. R. F. Webb (Ciba (A.R.L.), Ltd., Duxford). Several fellowships will be awarded for tenure during the academic year 1959–60 at Continental universities or institutions for research in chemistry, physics or some other allied scientific subject. They will be awarded to graduates of universities in the United Kingdom or the Republic of Ireland. The basic award for Fellows who wish to continue postdoctorate studies will be £800 per annum plus allowances. For candidates who have obtained a first degree in science and wish to undergo training in research, the basic award will be £500 per annum plus allowances. The total value of each fellowship will be determined by the advisory panel, and will be sufficient to cover the Fellow's living and other expenses (including fees and cost of travel) during the tenure of his fellowship, which will be for one year, renewable for a further one or three years. Applications should be made in duplicate on forms obtainable from the Secretary of the Ciba Fellowship Trust, Ciba (A.R.L.), Ltd., Duxford, Cambridge. The closing date for such applications is January 31, 1959.

C.S.I.R.O. Wool Research Laboratories

The three Wool Textile Research Laboratories of the Commonwealth Scientific and Industrial Research Organization (Australia) have been made divisions of the Organization. The Melbourne Laboratory becomes the Division of Protein Chemistry, the Sydney Laboratory the Division of Textile Physics, and the Geelong Laboratory the Division of Textile Industry. In future this group of divisions will be called the C.S.I.R.O. Wool Research Laboratories. These laboratories were established in 1949. The officer-in-charge of the Melbourne Laboratory, Dr. F. G. Lennox, becomes the chief of the Division of Protein Chemistry; the officer-in-charge of the Sydney Laboratory, Mr. V. D. Burgmann, becomes chief of the Division of Textile Physics; and the officer-in-charge of the Geelong Laboratory, Dr. M. Lipson, becomes chief of the Division of Textile Industry.

Annual Conference of Educational Associations

The forty-second annual conference of Educational Associations will be held in the College of Preceptors, 2 and 3 Bloomsbury Square, London, W.C.1, during December 30–January 2. Dr. B. E. Lawrence, chief education officer, Essex, will deliver the presidential address entitled "Partnership in Education" on the eve of the Conference in the assembly hall of the Institute of Education, University of London. During the Conference, and under the auspices of the School Nature Study Union and the Universities Federation for Animal Welfare, Miss F. R. Elwell, science producer, B.B.C. Television for Schools, will give a lecture on "Animals and Television" in the College of Preceptors on December 31 at 2.30 p.m. All meetings at the Conference are open free of charge and without tickets. Further information can be obtained from the Conference Secretary, 2 and 3 Bloomsbury Square, London, W.C.1.

Geographical Association Summer Schools

The Geographical Association is organizing two summer schools in 1959. The first, to be held in Spain during August 12–27, under the direction of Dr. M. J. Houston (Oxford), will deal with Mediterranean geography. On this course members will study the land-forms and vegetation climaxes on the northern and southern flanks of the central Pyrenees; contrasts in relief, vegetation and land use in the central cordillera of Spain (field excursions from Madrid); and distinctive types of land use and settlement in Valencia and Catalonia (field excursions from Valencia and Barcelona). Urban studies will be made in Madrid, Valencia and Barcelona. The second, to be in Switzerland during August 18 September 2, will consist of Alpine studies centred on Orsières in the Pennine Alps, near the Italian and French frontiers. It will be under the direction of Mr. R. C. Honeybone (London). Members will study the Alpine environment of the Drance River and its tributaries, and its physical and cultural relations with, to the north, the Rhône valley (Martigny and Sion) and, to the south, Val d'Aosta via Grand St. Bernard; a field excursion to study glacial features near Chamonix will be included in the programme. Members' field work and several of the field excursions will be done on foot, which will involve hill-walking and climbing but not rock-climbing. Further details and forms of application can be obtained from the Assistant Secretary, Geographical Association, c/o The Park Branch Library, Duke Street, Sheffield, 2.

University News: London

Dr. J. A. Laing, reader in the University of Bristol, has been appointed to the Courtauld chair of animal husbandry and veterinary hygiene tenable at the Royal Veterinary College.

The title of professor emeritus of plant physiology in the University has been conferred on Prof. F. G. Gregory on his resignation on December 31 from the chair of plant physiology at the Imperial College of Science and Technology, which he has held since 1937.

Announcements

The insignia of C.B.E. has been presented by the British Ambassador in Rome to Prof. Domenico Marotta. As director-general of the Istituto Superiore di Sanità in Rome, Prof. Marotta has an important position in chemical science and industry in Italy, and organized the meeting this year of the Eighth National Congress of the Italian Chemical Society jointly with the Society of Chemistry and Industry.

The Worshipful Company of Founders has awarded its medal in bronze to the following Liverymen of the Company to mark "their services to the Art and Mystery of Founding and to the Company": Dr. J. G. Pearce, director of the British Cast Iron Research Association; Dr. J. E. Hurst, managing director of Bradley and Foster, Ltd., Darlaston; Mr. C. C. Booth, director of Booth and Brooks, Ltd., Burnham-on-Crouch; and Mr. J. J. Sheehan, lately managing director of the Coneygrw Foundry, Ltd.

Mr. William Barr has been nominated by the Council for election as president of the Iron and Steel Institute for the 1959–1960 session. He will take office at the general meeting on May 6.

In February 1956 the National Metallurgical Research Laboratory of the Council of Scientific and Industrial Research, Jamshedpur, India, held a symposium on "Production, Properties and Application of Alloy and Special Steels". The forty-five papers contributed are now published (pp. vi+488. Jamshedpur: National Metallurgical Laboratory, 1958), and cover all the main aspects of the subject. Most of them are from Indian workers, but a dozen or so represent contributions from metallurgists in Europe and America.

THE NATIONAL CHEMICAL LABORATORY

THE National Chemical Laboratory, Teddington, of the Department of Scientific and Industrial Research, held a series of open days during October 21–24. In this article there is space to describe only some of the items on view.

Improved laboratory and semi-scale techniques for separating the rare earths have been developed, and considerable amounts of the individual oxides have been accumulated. Increased availability of these materials has prompted a search for new uses. A recent application of thulium was the subject of a very attractive display. When the pure oxide is irradiated in a high neutron flux, soft γ- and X-rays are emitted which can be used in engineering and medical radiography, and a number of interesting radiographs taken at the Atomic Energy Research Establishment, Harwell, were shown. The source unit consists of a small pellet of sintered thulia enclosed in an aluminium capsule.

The use of zone-refining for purifying materials used in researches on semiconductors, such as indium, tellurium, bismuth and aluminium, also attracted interest. The difficulties of following the course of purification by conventional analytical methods are considerable, and when possible, the movement of impurities is followed by introducing radioactive tracers; for example, the removal of silver from bismuth was effected by using radioactive silver as tracer. Other exhibits included the Department's collection of pure metals, and the recovery of valuable materials from industrial wastes.

In conventional processes for the extraction of uranium, it is necessary, after leaching the ore, to separate the barren solids from the uranium-bearing liquor; this liquid/solid separation represents a considerable percentage of the cost of extracting uranium. It has been found, with certain ores and with the correct degree of grinding, that satisfactory uranium extractions can be obtained by means of a limited contact between the aqueous leach pulp and the extracting solvent. This principle is employed in the disk contactor: the disks are wetted by the aqueous phase, and, as they rotate, a film of the aqueous solution is carried through the solvent, so effecting transfer of uranium.

Plastic standards for radiometric assay of uranium have been prepared by mixing 'Bakelite' moulding powder with pitchblende, the density of the standard being varied by addition of heavy fillers to the mixture before moulding. These standards, designed for use with prospectors' field ratemeters, possess the advantages that they are not liable to contamination or spillage and that they are not affected by changes in humidity or possible loss of radon.

Tests of the resistance of metals to corrosion and of the effectiveness of corrosion inhibitors are being made in water circulation systems at different speeds and temperatures of the water. The object of the work is to find means of reducing losses due to corrosion in industrial cooling systems.

*Cyclo*hexylamine carbonate has been applied by the Laboratory as a volatile corrosion inhibitor, and has given promising results in the protection of boilers and other steel equipment during shut-down periods.

The rate of oxidation of clean, pure iron is being measured by methods sensitive enough to detect the formation of less than one-tenth of a complete molecular layer of oxide per minute. The pressure in the apparatus can be controlled from less than 10^{-6} mm. mercury upwards.

Among various physico-chemical equipment for the examination of organic compounds was a simplified double-beam infra-red grating spectrometer using a 'Merton – National Physical Laboratory' replica as the dispersing element. The instrument is intended for chemical applications, both in analytical and structural diagnosis. The design allows solvent compensation to be achieved, and expansion of any part of the scale as required.

The stock of standard organic compounds available for distribution now includes fifty-five individual compounds. During the year, 395 samples were sent out to forty-five laboratories.

There is considerable interest at present in the development of materials of improved thermal stability for use as plastics, lubricants, hydraulic fluids, surface coatings, etc. A variety of organometallic compounds shows promise in this connexion, and work on this project has recently been initiated at the Laboratory. At present, attention is mainly directed to the boron-nitrogen and related systems.

Novel types of redox resins have recently been developed at the Laboratory. These resins are capable of undergoing true electron-exchange, that is to say, operating reversibly on an oxidation-reduction cycle. The new materials displayed were based on cellulose and polyvinyl alcohol and some of their potential applications were illustrated.

A knowledge of the molecular weights and molecular-weight distributions of commercially important polymers is of great importance to the polymer industry. A comprehensive survey of work in progress included the determination of the molecular weights and shapes of polymers by viscometry, osmometry, light-scattering photometry, and ultracentrifugation. Other exhibits showed the results of fractionation of polymers according to their chain-lengths, and the molecular weight distribution curves derived from these experimental studies.

Another facet of the work, namely, research on the synthesis of new types of ion-exchange resins and membranes, was also shown. Materials of this type are of great value in water treatment and extraction of valuable organic and inorganic substances from solution.

Microbial activities which have economic importance are also being studied. One extraordinary microbe needs no organic food—it lives on a simple diet of sulphur, mineral salts and air, and produces strong solutions of sulphuric acid. This organism is responsible for extensive damage to concrete structures such as water-cooling towers and sewage conduits. The use of sulphate-reducing bacteria to produce sulphur from sewage sludge and gypsum was illustrated. Demonstrations were given of the preservation of pure cultures of bacteria by freeze-drying; the bacteria can be revived after many years with unchanged properties. The number of strains held by the National Collection of Industrial Bacteria is about 1,100, from which 1,700 cultures were sent out during the past year.

FUNDAMENTAL RESEARCH IN SAFETY GLASS

THE Fundamental Research Laboratory of the Triplex Safety Glass Company at Holly Grange, Balsall Common, held an 'At Home' on November 14, to show the progress made since its official opening in December 1957. The main objective of the Laboratory is to establish the fundamental scientific background to safety glass manufacture and especially that of the toughened or tempered types which are produced by heat treatment. The work of the Laboratory falls roughly into four sections: toughened glass structure; physical chemistry; optics; and mechanical properties.

Work on the determination of the atomic structure of heat-treated glasses was shown in the X-ray, Electron-Microscopy and Thermodynamics Departments. Of special interest in connexion with X-ray investigations was a microdensitometer designed and built in the Laboratory.

Methods of producing safety glass by chemical means involving ion- and atom-exchange were shown in the Physical Chemistry Laboratory. Experimental low-temperature alloys for use as bus-bar material in glasses coated with gold film were also on view.

The work displayed in the optics section included stress measurements on toughened glass using Babinet and Sénarmont methods, together with interferometric methods of measuring the thickness of thin metallic films on glass. This latter was in connexion with the use of gold films, approximately 60 A. thick, which are used as heating elements on aircraft and other windscreens. Micro-hardness techniques to evaluate the surface properties of glass with special reference to abrasion resistance were also shown, together with apparatus for determining the light transmission of aircraft windscreens.

The results of investigations towards producing safety-glass components with less scatter in mechanical properties were on view in the Heat Treatment and Mechanical Properties Departments, where the application of schlieren methods for the study of the action of air jets used in the quenching process evoked much interest. The application of strain-gauge techniques to the evaluation of stress occurring in large glasses was also demonstrated.

THIRD INTERNATIONAL SEAWEED SYMPOSIUM

THE third International Seaweed Symposium was held in Galway, Ireland, during August 13–15, when some 220 scientists and industrialists from twenty-seven countries in Europe, Asia, Africa and the Americas attended. (The first and second Seaweed Symposia were reviewed in *Nature*, 170, 478; 1952; and 176, 1106; 1955.) The symposium was opened by Mr. Seán Lemass, Minister for Industry and Commerce, who welcomed the delegates to Ireland.

Our knowledge of the physical structure of the cell-wall of many algae has been greatly increased within recent years by new techniques such as polarization microscopy, electron microscopy and X-ray diffraction analysis, and these were reviewed by Prof. R. D. Preston (England). The chemistry of the polysaccharides of the brown, red and green algae was covered by Prof. E. L. Hirst (Scotland), and Dr. H. M. Ulrich (Austria) dealt specifically with alginic acid and its derivatives both from the chemical and industrial points of view.

Nine papers were devoted to the chemistry of the carbohydrates, proteins and other constituents of the red algae. Low molecular compounds were discussed by Mr. B. Wickberg (Sweden). Further interesting glycosides have recently been isolated; for example, '*iso*floridoside' is a mixture of diastereoisomers (1-O-α-D-galactopyranosyl D- and L-glycerol), while O-α-D-galactopyranosyl (1 → 6)-O-β-D-galactopyranosyl (1 → 1)-glycerol, which occurs in wheat flour lipids, has been found in two red algae. Dr. J. R. Turvey (Wales) dealt with the polysaccharides of *Porphyra umbilicalis*, which include a galactan sulphate, floridean starch, mannan and xylan; the galactan sulphate contains D-galactose, 6-O-methyl-D-galactose and 3 : 6-anhydro-D-galactose. 3 : 6-Anhydro-galactose is now a common constituent of red algal galactans. 6-O-Methyl D-galactose has been isolated from several *Porphyra* species, and Dr. J. C. Su (Formosa) reported its presence in *P. crispata*. The mucilage of *Gloiopeltis furcata* appears to be composed chiefly of agarobiose units, as in the case of the main polysaccharide ('agarose') of agar-agar. Prof. P. S. O'Colla (Ireland) discussed the constitution of the mucilage from *Laurencia pinnatafida*, which contains galactose, xylose, galacturonic acid and sulphate; the branched structure contains a 1 : 3-linked galactan backbone. A somewhat similar structure has been assigned to the gelatinous polysaccharide of *Furcellaria fastigiata*. Dr. E. G. Young (Canada) pointed out the many difficulties encountered in examining the amino-acids, peptides and proteins of *Chondrus crispus*; about 20–30 per cent of the protein nitrogen could not be solubilized, but the distribution of amino-acids in this insoluble protein was similar to other algal proteins; 80 per cent of the total nitrogen extracted was dialysable. Dr. Young also discussed the stability of carragheenin in dried *C. crispus*, which is of considerable importance to the seaweed industry; intrinsic viscosity and gel strength decreased markedly after storing the weed at 4°, 10° and 20° C. for two years, indicating degradation of carragheenin in the plant. Mr. M. O. Reachtaire (Ireland) read a paper on phycoerythrin and phycocyanin, and the absorption spectra and structure of these chromoproteins were discussed. Dr. C. Ó hEocha (Ireland) described the occurrence and distribution among a number of red algae, particularly in the Rhodomelaceae, of four water-soluble fluorescent substances; these were extracted, separated by chromatography, and characterized by their absorption spectra. One compound from *Laurencia pinnatafida* was obtained in crystalline form and its probable structure determined.

The polysaccharides of *Acrosiphonia centralis*, a green alga closely related morphologically to *Cladophora rupestris*, were reported by Dr. E. Percival (Scotland); partial hydrolysis of a sulphated polyuronide gave chiefly glucose, xylose, rhamnose and oligouronic acids composed mainly of rhamnose and glucuronic acid, and comparisons were made with the polysaccharides from *C. rupestris* and *Ulva lactuca*. Present evidence suggests that the green algae are the most complex from the chemical point of view.

Several communications were devoted to alginic acid and the alginates. The seventy-fifth anniversary of its discovery was marked by a short biographical sketch of E. C. C. Stanford by Dr. T. Dillon (Ireland). The seasonal variation in the alginic acid content of *Ascophyllum nodosum* was discussed by Mr. D. T. Flood (Ireland), while the effect of species, habitat, pre-treatment of the seaweed and isolation procedures on the viscosity of alginate solutions was covered by Mr. A. Haug (Norway). Methods for determining alginic acid were reviewed by Mr. M. F. Van der Lande (France), and details of the copper acetate and a new potentiometric titration method were given. The precipitation of sodium alginates of different degrees of polymerization by salts of lead, calcium, nickel and manganese was shown by Mr. R. H. McDowell (England) to be a complex problem and highly dependent on alginate concentration. The birefringent properties of alginate and carragheenate with colloid cations, for example polyglucosamine, were demonstrated by Dr. L. Langmaack (Germany), and there is a possibility that the phenomenon known as *Symplexionotropie* may be responsible for the formation of ordered structures in the plant *in vivo*. Dilute acid extracts of some brown algae contain phenolic reducing compounds known as 'fucosan', which are located in the physodes and are responsible for the brown colour formed in alkaline seaweed extracts; the fucosan content of *A. nodosum* was reviewed by Mr. A. Haug (Norway), and the influence of habitat on this and other constituents was discussed by Mr. B. Larsen (Norway), who also gave details of the influence of season, habitat and age of tissue on the niacin content of brown algae. The minimum number of plants required to give a representative sample for chemical analysis has been a vexed question for many years; in a paper on the statistical analysis of a large number of *Laminaria cloustoni*, Mr. F. T. Walker (Scotland) suggested 120 plants grouped according to haptera levels.

Both chemical and enzymic methods for removing sulphate groups from carbohydrates are of extreme importance in the elucidation of structure of the many algal polysaccharide sulphuric esters, and these were reviewed by Dr. P. F. Lloyd (Wales), who went on to describe the action of the sulphatases of *Patella vulgata* on fucoidin, chondroitin sulphate and keratosulphate. Further work in this field is awaited with interest. The use of the mass spectrometer in carbohydrate problems was outlined by Mr. P. A. Finan (Scotland); the potentialities of this ionization technique are immense in structural and conformational studies. Dr. C. C. Burt (Scotland) described the results of animal experiments with sodium laminarin sulphate as a blood anticoagulant; in rabbits and dogs, single doses of 20 mgm. per kgm. were well tolerated, but daily injections over 1–2 weeks produced toxic symptoms; the cause of this toxicity was discussed.

The occurrence and utilization of algae in the Caribbean and Morocco were discussed by Mr. W. D. Richardson (British West Indies) and Mr. G. Apikian (Morocco), respectively. The value of two New Zealand species, *Pachymenia himantophora* and *Durvillea antarctica*, as a fertilizer was assessed in a paper read by Mr. M. O. Reachtaire (Ireland). The interesting work being carried out in Norway on the use of seaweed meal as a supplement in animal feeding-stuffs was reported at the last symposium; Prof. J. Höie and Mr. A. Jensen (Norway) described further trials with chicks, hens, rats and sheep. The attitude of industry towards the research institute was assessed by Mr. E. Booth (Scotland) with particular reference to seaweed.

Critical observations on the taxonomy, ecology, growth and development of single species of marine algae formed the basis of several papers presented in the botanical sessions of the symposium. Dr. P. S. Dixon (England) showed that season and environment cause considerable morphological variation in *Pterocladia pinnata*, with the result that there has been taxonomic confusion in this species. Considerable variation was also noted by Dr. G. T. Boalch (England) in pure cultures of *Ectocarpus confervoides*, grown under different physiological conditions. The culture, growth and differentiation of *Caulerpa prolifera* were discussed by Prof. W. P. Jacobs (United States), who carried out experimental work on this species in the Naples Marine Laboratories.

Little has been reported on the effects of growth substances on the growth and development of marine algae. Dr. L. Provasoli (United States) found that, in bacteria-free cultures of *Ulva lactuca* (in sea-water media enriched with vitamins), the initiation of new germlings and the length of atypical filaments were increased by the combination of kinetin and indolacetic acid. Conspicuous elongation of the filaments was promoted by the addition of gibberellins to the kinetin–indolacetic acid combination.

An interesting account of *Monostroma* culture in Japan was given by Prof. T. Segi (Japan). It was shown how the results of a study of zoospore development in this species were of value to those concerned with its commercial culture. It is used for food as 'Aonori'.

The effects of environment on the development of *Fucus vesiculosus*, growing on an exposed shore and in an enclosed bay, were explained by Prof. W. R. Müller-Stoll (Germany).

Mr. H. T. Powell (Scotland) proposed that of the fifteen or so *Fucus* species currently recognized in various parts of the world, only five (or six) should be accorded specific rank. The species are *Fucus serratus* L., *F. vesiculosus* L., *F. ceranoides* L. emend., *F. spiralis* L. emend. (or *F. sherardii* Stackhouse emend., still being investigated), *F. distichus* L. emend. Powell, and perhaps *F. virsoides* J. Agardh.

Studies of the growth of *Macrocystis pyrifera* at various depths in the sea were reported by Prof. F. T. Haxo (United States), who has developed techniques and instruments which should prove useful in similar studies of other attached seaweeds.

Mr. B. Grenager (Norway) explained how he was able to predict the distribution of *Laminaria digitata* f. *stenophylla* and *Ascophyllum nodosum* in unknown areas on the Norwegian coast, by a study of charts only. The predictions were later substantiated by field surveys.

Nitrogen fixation by terrestrial blue-green algae is well known, but as Dr. M. B. Allen (United States) pointed out, little is known of nitrogen fixation by marine organisms. Dr. Allen gave an account of how she is growing pure cultures of freshwater nitrogen-fixing, blue-green algae under saline conditions, and reported the effect of this on their capacity for nitrogen fixation.

Dr. M. R. Droop (Scotland) discussed evidence for and against the view that vitamin B_{12} may become a limiting nutrient for phytoplankton populations in the sea. The mass culture of marine phytoplankton was reviewed by Dr. G. E. Fogg (England), who concluded that it was unlikely to become a practical proposition, at least until harvesting difficulties could be overcome.

Dr. J. W. Kanwisher (United States) reported on a new method of continuous oxygen recording which has been used for measuring the photosynthetic and respiratory capacity of several intertidal algae.

Details of a method of physode estimation were given by Dr. E. Baardseth (Norway), who found that the percentage physode volume varied from species to species and in *Ascophyllum*, with variation in salinity and habitat.

Prof. H. A. von Stosch (Germany) discussed similarities between the leucosin of diatoms and chrysomonads and the laminarin of Phaeophyta. He gave evidence to support the conclusion that these substances are closely related.

The main symposium was followed by a single-day symposium on "Intertidal Ecology".

The time available for discussion following each paper was very limited, but there were ample opportunities for private discussion at the various shore-collecting excursions and social functions run in connexion with the symposium. It was agreed that the complete text of the papers presented should not be published. The fourth International Seaweed Symposium is to be held in France in September, 1961, and an Advisory Committee consisting of Prof. T. Braarud (Norway), Dr. T. Dillon (Ireland), Prof. T. Levring (Sweden), Dr. A. D. de Virville (France), Dr. F. N. Woodward (Great Britain) and Dr. E. G. Young (Canada) was appointed to assist the French National Committee in drawing up a programme.

E. T. DEWAR

INTERNATIONAL CONFERENCE ON SCIENTIFIC MEASUREMENTS

AN international conference on the theoretical and practical problems involved in making scientific measurements was held in Budapest during November 24–29. Part of the conference was held in the building which was formerly the Stock Exchange but is now the home of the engineering societies and is re-named Technika Háza. The other meetings were held in the Rózsa Ferenc House of Culture. Some 250 foreign and 460 Hungarian scientists took part in the conference, and representatives came from twenty-three countries. Academies of science in a number of countries, including France, Italy and Sweden, either sent representatives or gave their official support to the conference.

Some 160 papers were read, 127 of them by non-Hungarian scientists. The papers were divided into a number of sections with the following titles: mechanical and optical, electrical and electronic, thermal, physico-chemical and nuclear-physical. There were also papers on the economics of instrument production, and an informal discussion was held between the university teachers present to discuss student courses for measuring techniques and instrument-making. Though there were many papers of considerable individual merit, one difficulty emerged during the conference, namely, that in some sections the papers were too diverse in character to form a coherent whole. Summaries of most of the papers were published in two booklets, mostly in the German language, though some were given in English, French or Russian.

The Hungarian Chamber of Commerce arranged an exhibition of Hungarian scientific instruments in the Technika Háza. The well-known skill of Hungarians in arranging exhibitions was clearly shown here. Though there were gaps in the range of instruments exhibited, the level of instrument technology in the fields covered appeared to be high.

This conference was called by three organizations acting jointly, one Hungarian, one in the Soviet Union and one in Poland. The Presiding Council hopes to prepare a further conference, probably in 1961, and to enlarge the national representation on the committee which will organize it.

Visits to scientific institutes in the Eötvös Lorand and the Technical Universities and in the Academy of Sciences were arranged. There was also a social programme which included visits to the opera, theatre and cinema. Those attending the conference were very conscious of their debt to the members of the staff of the Hungarian Federation of Scientific Societies for the care which they took in ensuring the comfort and the convenience of visitors.

W. A. WOOSTER

THE FUTURE OF ANTARCTICA

"THAT a new era in Antarctica indeed is opening needs clearer recognition. Suddenly Antarctica now has applied to it the resources, the techniques and the wealth of experience from no less difficult operations in the Arctic. The United States pre-eminently, and Russia not far behind, both possess and feel it expedient now for the first time to use great resources in Antarctica on a scale without precedent. Their northern experience is immense. Yet great resources of men and materials are not deployed by even the very powerful without strong reasons."

"Political stability in Antarctica in the next few years is certainly improbable. The post-war realignment of the nations in terms of modern power and resources is now in process of extending to Antarctica. . . . Now is the time for realism and re-appraisal by the sovereign states of Antarctica."

These quotations from the published version* of the lectures delivered by Dr. G. C. L. Bertram while he was William Evans visiting professor in the University of Otago in 1957 indicate well the nature of his theme. Dr. Bertram, who was director of the Scott Polar Research Institute at Cambridge during 1949–57, speaks with authority about Antarctica, and in this thought-provoking essay he speaks with evident concern. He recognizes and discusses five motives that may underlie rational activity in Antarctica—the adventurous, economic, scientific, political and strategic motives, and from his discussion there emerges a picture of the present situation in which the last two named are dominant, a situation in strong contrast to that which obtained in the first twenty years of this century when British expeditions dominated the Antarctic scene and interest was primarily adventurous and secondarily scientific. Dr. Bertram examines the probable motivation of the twelve nations that may be said to-day to have Antarctic 'aspirations' or 'interests'. Five of these—Australia, France, Great Britain, New Zealand and Norway—lay formal claim to sectors of Antarctic territory which cover about four-fifths of the continent. The sovereignty of these five mutually recognizing Powers is, however, not admitted by the United States and the U.S.S.R., the two Powers deploying greatest resources in the Antarctic, and is openly flouted by others. Time, Dr. Bertram insists, is not upon the side of the five, and their position is not helped by their comparative grave weakness in shipping suitable for the maintenance of their Antarctic interests. "Not one of the five," he remarks, "has the full manœuvrability and appearance of power only to be given by the possession of a genuine ice-breaker. On the other hand, Russia, the United States and Argentine have admirable such vessels, and even Chile has building a ship superior to anything possessed or yet being built by the five. Our grandfathers must turn in their graves at this astonishing change in maritime power and forethought and at the depths to which the British Commonwealth has sunk." There is an over-riding need, Dr. Bertram thinks, for consultation by the five, and first and especially by the three Commonwealth countries, and a re-appraisal leading to a constructive plan. "When the passage of time may seem to give advantage to the rival or adversary, then it is often rationally expedient to seize the initiative."

Dr. Bertram considers some of the theoretical possibilities for the future political evolution of Antarctica, namely, recognition of existing claims (and here he notes how much this would be aided if the United States even now were to lay claim, as it has excellent reason for doing, to the remaining unclaimed Pacific sector); sale of Antarctic territory; condominium, possibly under the United Nations Organization; partition into territories each administered by members of the United Nations in trust; and finally, what he calls the "functional approach" whereby the powers of existing international and technical organizations, such as the International Civil Aviation Authority or the World Meteorological Organization, should be recognized as providing the effective authority within their spheres of activity. This functional approach is attractive, but whatever the mode of evolution favoured, Dr. Bertram is clearly right in calling for some immediate and realistic thinking, both in Britain and in the Commonwealth, concerning our Antarctic aspirations and responsibilities.

ROTHAMSTED EXPERIMENTAL STATION

REPORT FOR 1957

EVERY year, when reading the annual report of the Rothamsted Experimental Station*, one is impressed anew by the scope of the work undertaken by Britain's oldest agricultural research centre. Not only British but Commonwealth problems receive regular attention, a fact well shown by the list of overseas visits and secondments of staff for the purposes of specialist consultation or investigation. The present report is the fiftieth of the series, and a valuable inclusion is a summary index covering this period. It is, indeed, a concise history of the development of Rothamsted in the present century.

Comprising, as it does, the work of fifteen departments as well as such activities as soil surveys at home and abroad, it is not possible for any single reviewer to discuss critically all the varied information contained in the report. The main lines along which research is proceeding may, however, be indicated.

In the Physics Department work has continued on the structure and properties of soil, particularly clays. Studies on these suggest that, when they are wetted slowly, subsequent flooding does not produce the slaking effect that it has on a dry clay and that the shattering effect of entrapped air seems to be very slight. The practical effect of this seems to be that, in a saturated atmosphere, the slaking action of rain on dry field soil is confined to the surface, since the diffusion of water vapour downwards ahead of the liquid wetting front permits a controlled swelling of the clay without disruption. Other investigations have dealt with temperature and water relations in soil and with crop environment with particular emphasis, during the period under review, on spring wheat. It has been shown that short-period fluctuations in the rate of water uptake by wheat follow closely the changes in sunlight intensity.

The Chemistry Department has continued its experiments on the use of fertilizers and it is clear that seasonal variations in crop response to nitrogen are so large that it is not yet possible to make practical recommendations to the farmer with the certainty that he would like. This is not surprising since the maximum profit from any particular crop does not depend on one factor alone. One interesting finding was that heavy dressings of calcium nitrate damaged germination and early growth of all crops, while under the same conditions an equivalent amount of ammonium sulphate was harmless. Alternatives to superphosphate have been tested, but none so far has proved superior to this well-tried substance, a fact, surely, that would have gratified Rothamsted's founders. Work has continued in the Pedology Department on the mineralogy of soil components, the determination of which is of great help to the Soil Survey. Materials from Britain and from abroad have been studied, and a number of unusual minerals identified.

---

* Rothamsted Experimental Station (Lawes Agricultural Trust). Report for 1957 (With 50-Year Index, 1908–57). Pp. 316. (Harpenden: Rothamsted Experimental Station, 1958.) 10s.

The nitrogen cycle and the ecology of soil micro-organisms remain the two major interests of the Soil Microbiology Department. The relationship between *Rhizobium trifolii* and its phage has been studied, and changes in the latter have been noted during storage in artificial soil. A fungistatic action by certain aerobic spore-forming bacteria has been demonstrated in all soils examined except those with a strong acid reaction, and it is suggested that such bacteria may be responsible for fungistasis in natural soil in the field. Other investigations have concerned the bacterial decomposition of herbicides and cellulose.

Various aspects of plant nutrition and growth have continued to interest the Botany Department, particularly the effect of nutrients on root and leaf growth. The known relation of leaf area to crop yields makes such studies of considerable practical interest. The effects of nitrogen, phosphorus and potassium on leaf area have been examined, as was that of gibberellic acid. The effect of this last was one of increasing the leaf area rather than the photosynthetic activity of the plant. A foliar application of gibberellic acid to potato increased leaf area and crop yield but caused some malformation of the tubers.

Plant enzymes engaged the attention of the Biochemistry Department, and an article on "Bracken Thiaminase" by R. H. Kenten is included in the report. This study has not yet produced results of practical application in bracken eradication, but a useful and necessary start has been made in acquiring the basic knowledge essential to a solution of this most important agricultural problem.

The contribution of Rothamsted to our knowledge of plant viruses is universally appreciated and needs no advertisement. The Plant Pathology Department is as active as ever in this field and much detailed and fundamental research continues. Electron microscopy has added much to our knowledge of viruses, but advances in technique are needed for this tool to be fully exploited. Possibilities in this direction are under continuous examination, and the published work of the Department is proof of the progress made in this very critical matter. In addition to the better-known plant viruses, those of cereals and grasses have received attention. Yellow dwarf virus is increasing in cereal crops in Britain, but more needs to be known concerning its effect on yield. Results recorded here suggest that this is more severe on oats than on wheat and barley. The susceptibility of various grasses to infection by cereal viruses and the identification of their vectors have also been studied.

Work on eelworms of economic importance and their predators has been the concern of the Nematology Department, while the Insecticides and Fungicides Department has continued the study of the pyrethrins and the effect of environmental conditions on the toxicity of various insecticides and fungicides.

The Entomology Department is working on various aspects of the biology and ecology of insect pests, in particular, aphids, frit fly, gall midges and the wheat bulb fly. The study of the behaviour, physiology, nutrition and the diseases of bees has been continued by the staff of the Bee Department.

Statistics have always figured largely in the work of Rothamsted, and the installation of an electronic computer has increased both the range and the volume of the work of the Statistics Department. In addition to work on the Station's own experimental data, help has been given to outside institutions in planning experiments and analysing results.

The report includes a list of the field experiments now in progress on the Rothamsted and Woburn farms and an account of the year's progress in the Soil Survey of England and Wales. Accompanying the article on bracken thiaminase already mentioned are papers by Mary D. Glynne and G. A. Salt on "Eyespot of Wheat and Barley" and by R. G. Warren on "The Residual Effects of the Manuring and Cropping Treatments in the Agdell Rotation Experiment".

The list of contributions to scientific journals made during the year with which the report ends bears evidence of the industry with which current problems are being investigated at Rothamsted and are a tribute to all concerned. J. H. WESTERN

EAST AFRICAN AGRICULTURE AND FORESTRY RESEARCH ORGANIZATION

REPORT FOR 1957

THE East African Agriculture and Forestry Research Organization is an inter-territorial research organization administered by, and forming part of, the East Africa High Commission. It is jointly financed by the three East Africa Territories of Kenya, Tanganyika and Uganda, the Protectorate of Zanzibar and the United Kingdom Government through the Colonial Development and Welfare Fund. The principal functions are to undertake long-term research work on behalf of the Territorial Departments of Agriculture and Forestry or to investigate problems which require highly specialized equipment or research officers. The present report (East Africa High Commission: East African Agriculture and Forestry Research Organization. Record of Research for the period 1st July, 1956, to 31st December, 1957. Pp. vii+112. (Nairobi: Government Printer, 1958.) Sh. 3/50) describes examples of each of these types of work and contains much of interest to all those concerned with agriculture and forestry in the tropics. The Physics Division in collaboration with the plant physiologist has continued to investigate the water relationships of plants and soils, and in particular have been concerned with problems associated with the most economical use of available water. This work also involves calculation of the amount of water which crops use from week to week, from simple meteorological and basic soil data. The prediction of crop responses of the soil and the build-up of nitrates in the soil due to decomposition of soil humus are two important aspects of the work of the Chemistry Division. It has now been shown that soil humus may be divided into two parts. One part is held by the soil and is resistant to decomposition even if the soil is kept warm and moist. The other much smaller part is in the soil solution and oxidizes rapidly under these conditions. Humus comes into solution when a dry soil is wetted, and the drier the soil before wetting the greater the amount of organic matter coming into solution. Thus, nitrates are only produced in the soil in appreciable quantities during the first rains after the dry season, and if leaching occurs there is not likely to be appreciable production of new nitrate later on. This emphasizes the need to get crops established as early as possible in the wet season. The Plant Pathology Division, starting with Central American varieties of maize, has successfully completed a breeding programme to give varieties resistant to tropical American maize rust, *Puccinia polysora*, a disease which first occurred in East Africa in 1952. Forestry investigations are mainly concerned with problems in the drier areas of East Africa. The Animal Nutrition Division has made extensive analyses of the main organic components of several local grasses at different times of the year, and the apparent digestibility of these grasses has been compared with those from temperate regions. Collecting of botanical specimens has actively continued and the services of the herbarium for identification of specimens has been in great demand from neighbouring territories.

ELECTRON RESONANCE STUDY OF THE RADICALS PRODUCED BY CONTROLLED POTENTIAL ELECTROLYSIS OF AROMATIC SUBSTANCES

By D. E. G. AUSTEN, Dr. P. H. GIVEN, Dr. D. J. E. INGRAM and M. E. PEOVER

British Coal Utilisation Research Association, Leatherhead, Surrey
and
Department of Electronics, University of Southampton

THE negative ions formed by electron transfer from sodium metal to hydrocarbon molecules in tetrahydrofuran solution have received much attention in the past year or so, and recently studies have been extended to the similar ions formed in the same way by carbonyl, nitro and cyano derivatives[1]. The same radical-ions have been postulated as the primary products of the polarographic reduction of aromatic hydrocarbons in dioxan-water[2] and of aromatic carbonyl compounds in the non-proton-active solvent dimethylformamide[3]. These inferences from polarographic behaviour have not hitherto been supported by any direct demonstration that the ions are indeed present. We wish to report such a demonstration, obtained by measuring the electron resonance signal given by solutions electrolysed under the polarographic conditions.

Anthracene, benzophenone and anthraquinone have been electrolysed (the apparatus and method are described in ref. 4) in 0·1 *N* tetraethylammonium iodide in dimethylformamide, using a stirred mercury cathode the potential of which was maintained at a value corresponding to the top of the first wave of each substance[4,5]. Under these conditions the polarographic evidence indicates that the paramagnetic mononegative ions should be formed (Fig. 1):

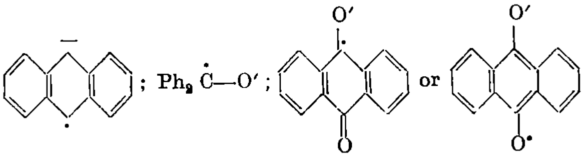

Fig. 1

At intervals during the electrolyses, samples were withdrawn under oxygen-free nitrogen into tubes of a size to fit the resonant cavity exactly. The tubes were immediately chilled in liquid nitrogen and sealed, and the signal was measured, a few hours later, in a 3-cm. wave-length electron resonance spectrometer. This employed an H_{014} rectangular cavity cooled to liquid-oxygen temperatures, and obtained high sensitivity by magnetic field modulation at 100 Kc./s., and phase-sensitive detection[6]. The

Table 1. Details of Reaction Conditions and the Products

Substance	$-E_{1/2}$ (volt) versus mercury pool	Controlled potential (volt)	n*	Concentration of solution (mM)	Max. concentration free radicals (mM)	Nature of product	Line-width (gauss)	g-value (± 0·001)
Anthracene	1·41, 1·88	− 1·55	2	40·1	0·31	Dihydroanthracene	18	2·005
		− 1·55	—	28·1	0·30

Anthraquinone	0·33, 0·90	− 0·5	1	12·7	18	Equimol. mixture anthraquinone + 9 : 10-diacetoxy-anthracene†	11	2·007

* n = Faradays of electricity/mole of reducible substance. † Product was acetylated.

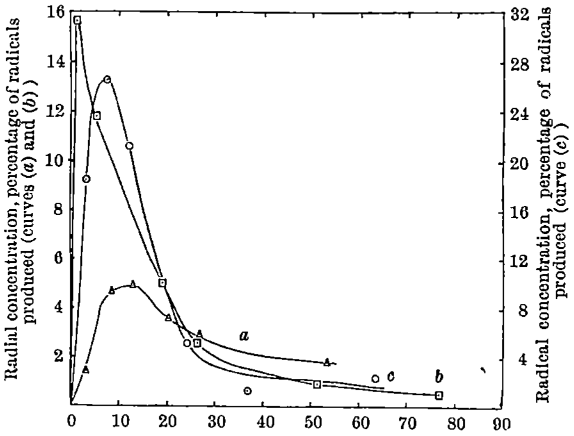

Fig. 2. Concentration of free-radical-ions as a function of degree of reduction: (*a*), Anthracene, 7·14 gm./l. (△); (*b*) anthracene, 5 gm./l. (▣); (*c*) benzophenone, 6 gm./l. (⊙)

concentrations of free radical were calculated by comparing the integrated signal strengths with those from standard samples, and the absolute accuracy of the results is estimated at about ± 20 per cent. The number of radicals produced by electrolysis was calculated from the quantity of electricity passed, which was measured with a coulometer.

Details of the experiments are shown in Table 1. Appreciable concentrations of radicals were found in the solutions of all three substances. Since the measurements were all made on materials in the solid state, considerable anisotropic dipolar broadening was present and no hyperfine structure was observed. The magnitudes of the line widths were found to vary somewhat with dilution, confirming the fact that dipolar interaction was the main source of broadening. It is seen that the anthraquinone radical-ion has a *g*-value appreciably shifted from that of the free spin (2·0023), and this suggests that there is some localization of the unpaired electron in this case.

The results are shown in Fig. 2, where the concentration of radicals in each sample is expressed as a percentage of the total number produced at the cathode up to the time of withdrawal of the sample (it should be noted that for anthracene and benzophenone this fraction could not exceed 50 per cent since, according to the mechanism to be described, all the molecules of aromatic substance are on the average reduced twice). 'Total reaction' signifies the passage of 1 or 2 Faradays per mole, as indicated in Table 1.

Anthracene and benzophenone gave the dihydro products in good yield although the controlled potential was less than that required for two-electron reduction; there was no evidence of dimerization. The curves show that the radicals produced from these substances are consumed fairly rapidly. It has been shown[7] that disproportionation of hydrocarbon mononegative ions:

$$2\,R' \rightleftharpoons R + R''$$

is energetically not feasible. We therefore suggest the following mechanism to account for the observations (Fig. 3):

$$\begin{array}{rll} R + \varepsilon & = R' & (1) \\ R' + \text{solvent} & = R\text{H}\cdot & (2) \\ \text{either } R\text{H}\cdot + R' & = R\text{H}' + R & (3a) \\ \text{or } R\text{H}\cdot + \varepsilon & = R\text{H}' & (3b) \end{array}$$

Fig. 3

Reactions 2 and 3*a* occur in the bulk of the liquid; the first of these must require activation and therefore be slow (that this is the mechanism of proton addition has been established[8] already). Hoijtink *et al.*[2] have shown that the radicals RH· derived from hydrocarbons always have higher electron affinities than the parent hydrocarbon molecules; moreover, electron-transfer reactions of the type of 3*a* are known to be rapid and not to require activation (for example, refs. 9, 10). Reaction 3*a* is therefore likely to be more important than 3*b*, and the RH· radicals will not make any significant contribution to the total concentration of radicals measured. The molecule R produced in 3*a* returns to the electrode and is reduced again. The difference in the results obtained in the two experiments with anthracene is probably due mainly to differences of temperature; heat is evolved during the electrolysis and an appreciable rise in temperature occurs in the early stages of reduction. Since the initial concentrations were different and moreover cells having cathodes of different area were used, the temperature history would have been different in the two experiments. If the temperature could be controlled, it would be possible to deduce the rate of protonation of R' from the results of experiments of this kind. The solvent used contained a small amount of water as impurity, but its molar concentration was less than one-fifth of that of the organic solutes, so that it cannot have made much contribution to the protonation by reaction 2.

The behaviour of anthraquinone is quite different from that of the other substances. Only 1 Faraday per mole was consumed. The concentrations of radicals measured in six samples collected during the electrolysis were very high; the values obtained were in fact all more than 100 per cent of those calculated from the initial concentration and the quantity of electricity passed, and rose from 109 to 150 per cent. These errors are mostly outside the expected limits of accuracy of the measurements and are difficult to account for. Some samples of the electrolysed solution were kept at room temperature for 6 hr. before measurement, and the observed concentrations of radicals were an appreciable fraction (20–40 per cent) of those obtained for the samples preserved in liquid nitrogen. This confirms that the rate of decay of radical concentration is small, and justifies the view

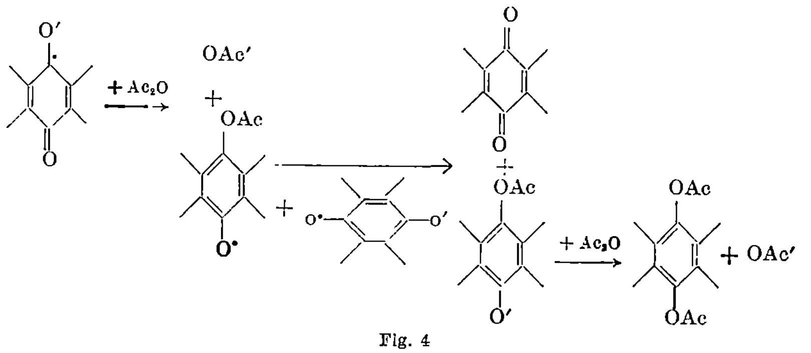

Fig. 4

that the fractional concentration is near 100 per cent throughout the electrolysis and that no protonation occurs. In order to facilitate identification of the product, acetic anhydride was added at the end of the electrolysis. The sequence of reactions shown in Fig. 4 can account for the result (that is, two moles free-radical-ion giving one mole each of the quinone and 9 : 10-diacetoxyanthracene).

Although the anthraquinone radical was stable enough to be examined at room temperature, it was not possible to observe any hyperfine structure, owing to lack of homogeneity in the magnetic field under the conditions that were used. The paramagnetic resonance spectrum of the 'semiquinone' of anthraquinone has been reported previously[11]; hyperfine structure was resolved and a *g*-value of 2·00403 quoted. However, it is not clear whether the species studied was the semiquinone itself or the semiquinone ion or the undissociated sodium salt. (For various views on the species of radical in the case of benzoquinone see refs. 12, 13.)

A CORRELATION BETWEEN SULPHUR CONTENT AND NET DIETARY-PROTEIN VALUE

By D. S. MILLER and D. J. NAISMITH

Human Nutrition Research Unit, National Institute for Medical Research, London, N.W.7

WITH the work of Willcock and Hopkins[1] and Osborne[2] the concept was established that the nutritive value of proteins could be interpreted in terms of amino-acid composition, or, in the light of more recent work[3], in terms of their content of essential amino-acids, and might therefore be estimated by chemical means.

Complete amino-acid analysis has much to commend it theoretically, but the methods available are frequently less accurate, more time-consuming and more expensive than the biological measurements used to monitor them. Furthermore, the most accurate amino-acid analysis of a protein does not necessarily provide an unequivocal basis for determining its nutritive value, or even the amino-acid limiting its value.

Attention has recently been focused on specific indispensable amino-acids in proteins. Of the chemical methods in current use, the measurement of 'available lysine' in protein concentrates, used in animal feeding, is most promising[4], but from inspection of the composition of human diets, containing proteins from many sources, the sulphur-containing amino-acids, methionine and cysteine together, rather than lysine, appear to be limiting. Where this is not the case (as, for example, in white flour[3]), they are frequently the second factor restricting nitrogen retention.

Rose[5] has remarked that "the diets consumed by a large part of the human race are known to be relatively low in methionine". Experimental evidence in support of this contention is found in the work of Miller and Dema[6]; 70 per cent of the human diets, assayed by biological methods, were shown to be effectively supplemented with methionine.

It therefore seemed to us that the determination of the total sulphur content of mixed diets might provide a simple chemical method for estimating the nutritive value of proteins.

A preliminary examination of biological data, taken from Block and Mitchell[3], and chemical figures from the food tables of McCance and Widdowson[7], relating to some twenty-five foodstuffs, revealed a correlation between their sulphur content and net protein value. (The correlation coefficient was 0·913; $P < 0{\cdot}001$.) By common usage, net protein value (= biological value × digestibility × per cent crude protein) is determined on animals fed semi-synthetic diets containing the test protein at 10 per cent level. In the present experiments, the biological measurements were made by the method of Miller and Bender[8], using freeze-dried human diets from various parts of the world. To avoid confusion in terminology, since these materials were fed without any artificial adjustment in composition, net protein value is here termed net dietary-protein value[9], and the diet is evaluated in terms of reference protein[10].

Total sulphur was determined by combustion of the material in a Berthelot–Mahler bomb, precipitation of the sulphuric acid so formed with benzidene hydro-

Table 1

Origin of diet in meal	6·25 × nitrogen (per cent)	Net protein utilization (per cent)	Net dietary-protein value (per cent)	Sulphur (mgm. per cent)

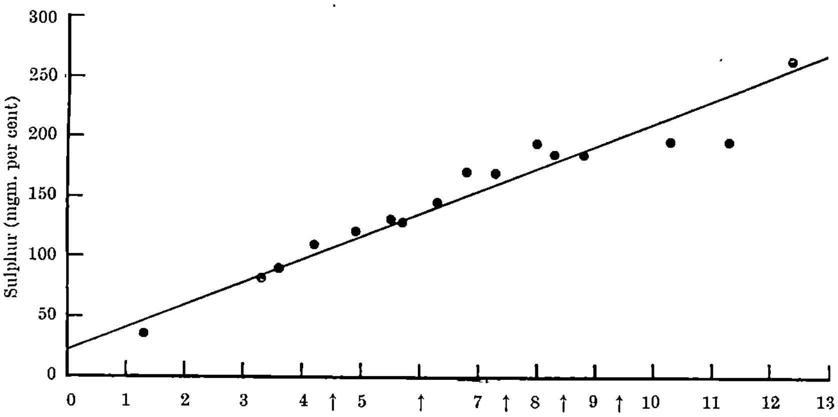

Fig. 1. Correlation between total sulphur content and net dietary-protein value (N.D.V.). Letters indicate 'safe practical allowance' for: *A*, adult; *C*, child; *T*, toddler; *B*, adolescent; *L*, lactating mother. N.D.V. = 0·0521 *S* – 1·06

chloride[11], and titration of the precipitate with standard sodium hydroxide[12].

The results are summarized in Table 1 and Fig. 1. Despite a wide variation in the percentage of crude protein and net protein utilization, a highly significant correlation between net dietary-protein value and total sulphur was found ($R = 0·967$; $P < 0·001$). In Fig. 1 this relationship is illustrated graphically, together with an indication of the 'safe practical allowance' for various age groups, calculated from the Food and Agriculture Organization report[10] by Platt and Miller[13].

In measuring total sulphur, no account is taken of the level of inorganic sulphate in the diet, the relative proportions of methionine and cysteine, or of the availability of these amino-acids. In addition, no allowance can be made with this method, or in fact with any chemical method, for the metabolic wastage of protein occurring at high levels of protein intake. It is, however, considered that none of these factors, with the possible exception of the last-mentioned, is likely to cause any serious error when dealing with complete human diets or meals.

We suggest, therefore, that the chemical method described above may provide a rapid means of assessing the nutritive value of proteins in human diets. As a further simplification, most of the chemical information may be abstracted from published data.

STUDIES IN SYNTHESIS OF DEOXYRIBONUCLEIC ACID

Radiobiochemical Lesion in Animal Cells

A MULTIPLICITY of biochemical changes have by this time been described in animals following lethal or sub-lethal exposure to X-radiation[1]. It may now be appropriate to see if any unification of these changes is possible.

The response detectable in an intact animal is complicated by the presence of dead cells and by the adjustments occurring within the tissues following X-radiation. These adjustments may include migration of cells, proliferation of surviving cells, etc., so that the interpretation of biochemical effects later than 1–2 hr. after exposure is very difficult. We are therefore only concerned here with disturbances which can be detected immediately after irradiation and with the effects of these biochemical changes in radio-sensitive and non-sensitive cells.

Reactions associated with two sites within the cell appear to be affected shortly after exposure.

1. (*a*) Phosphorylation of nucleotides bound by the nucleus[2] is 100 per cent inhibited 3 min. after 50–100 r.[3]. Such phosphorylation has so far been demonstrated in rat lymph nodes, thymus, spleen, intestinal mucosa and bone-marrow, but not in liver, brain, kidney and pancreas. (*b*) The well-established reduction of precursor uptake into deoxyribonucleic acid is detectable in rat thymus after as little as 25 r. and is 49 per cent of the control value by 3 min. after 1,000 r.[4,5].

2. (*a*) Rat spleen deoxyribonuclease II, which is present in either the mitochondrial or the lysosomal fraction of cell homogenates, is liberated into the supernatant fraction by 30 min. after 850 r.[6]. (*b*) Mitochondrial oxidative phosphorylation is uncoupled[7,8]. With succinate as substrate the effect is detectable in rat spleen mitochondria 4 hr. after 100 r. and in rat thymus mitochondria after 50 r. After 700 r. the reduction is apparent by 2 hr.[9]. (*c*) After irradiation, phosphorylation by spleen mitochondria responds[9,10] to added cytochrome *c*.

Synthesis of deoxyribonucleic acid is a property of dividing cells, and evidence has gradually been accumulating that this does not occur continually through the life of the cell but is restricted to certain periods. The work of Howard and Pelc[11] on bean-root tips and Lajtha and his colleagues[12] with human bone-marrow cultures has indicated that synthesis of deoxyribonucleic acid occurs during a limited period in interphase—the synthetic period (S)—which is preceded by a highly radiosensitive pre-synthetic period (G_1) but which is itself less sensitive. It seems likely that in cells which are going to divide changes

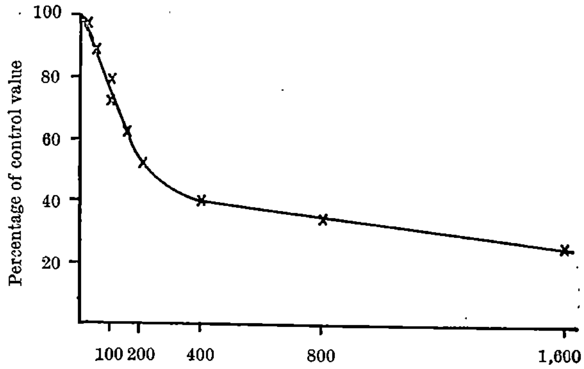

Fig. 1. The effect of total-body X-radiation on the incorporation of phosphorus-32 into rat thymus deoxyribonucleic acid 2 hr. after exposure

occur in G_1, which are an essential preliminary to the synthesis of deoxyribonucleic acid, and their inhibition by X-radiation would result in a failure of precursor uptake into deoxyribonucleic acid. The radiosensitivity of nuclear phosphorylation makes it attractive to suggest that this process may contribute to the radiosusceptibility of the pre-synthetic period. Either the phosphorylation of bound nucleotides is an essential preliminary to the synthesis of deoxyribonucleic acid, or the inhibition may be a delicate index of structural or functional changes within the nucleus not previously detected in other biochemical tests. Once the essential preliminaries have been completed, that is, the cell is entering *S*, higher exposures are required to prevent the final condensation of deoxyribonucleotides on the template.

A polyphasic response of synthesis of deoxyribonucleic acid to X-radiation is suggested from our results on the incorporation of phosphorus-32 into rat thymus deoxyribonucleic acid. The results show (Fig. 1) a very sensitive linear reduction in incorporation after 25–200 r., which is followed by a slowly increasing inhibition up to 3,200 r. It does not seem unreasonable to suggest that the initial portion of the dose–response curve corresponds to inhibition of nuclear phosphorylation and that the phase of only slowly increasing inhibition can be associated with progressive damage to the template.

A similar conclusion to this has also been reached by Lajtha, Oliver, Berry and Noyes (following communication) from autoradiographic studies of human bone-marrow cells exposed to either X-rays or α-particles in tissue culture.

These two facets of damage to the nucleus cannot be considered in isolation from the remaining part of the cell. The significance of the cytoplasm in the radiation injury has often been emphasized[13–15] and an excellent discussion of the relevant data has been provided recently by Trowell[16]. Alterations to mitochondrial reactions after exposure develop rather more slowly than those to the nucleus, but they lead to a decrease in production of adenosine triphosphate and to the liberation of enzymes, such as deoxyribonuclease II, which can exacerbate the nuclear damage. It seems probable that differences in radiosensitivity between dividing cells, lymphocytes and, for example, the liver, may be attributed to the part which the cytoplasm, and in particular the mitochrondria, can play in restoring or by-passing damage to the nucleus. In a dividing cell it is obvious that nuclear damage can prevent multiplication and, if rather large exposures are used, disturbances in the mitochondria may prevent any reversal of the nuclear disorders, although with smaller exposures mitochondrial alterations are slight.

In the non-dividing lymphocyte the volume of cytoplasm and number of mitochondria are very small[16]. Nuclear metabolism is therefore a major factor in the economy of the cell, and its inhibition may have serious consequences because of the inability of the cytoplasm to overcome the damage. In liver, on the other hand, it is likely that the relatively smaller contribution which the nucleus makes to the overall cell metabolism can perhaps be restored through the operation of the large mitochondrial reserve.

If the nucleus and mitochondria are the main regions affected within the cell, it is necessary to explain their susceptibility. Both these sites require oxygen and contain 'bound nucleotide'. Allfrey and Mirsky[17] have shown that treatment with deoxyribonuclease prevents nuclear phosphorylation, which may be restored by the addition of either deoxyribonucleic or ribonucleic acid, and Siekewitz and Watson[18] have suggested that bound nucleotide plays some part in mitochondrial oxidative phosphorylation. Ribonucleic acid–protein complexes are found in microsomes, and bound nucleotides may be part of the cell membrane ; but neither of these latter sites appears to be radiosensitive. It may be the participation of oxygen, possibly in some bound form, in nuclear and mitochondrial reactions which is the factor determining the sensitivity of these sites.

Mechanism of Radiation Effect on the Process of Synthesis of Deoxyribonucleic Acid

SYNTHESIS of deoxyribonucleic acid occurs only for a limited period of time in interphase[1,2]. Therefore, in studying the effects of radiation on the synthesis of deoxyribonucleic acid it is important to differentiate between effects on the pre- or post-synthetic period as opposed to the synthetic period itself (process of deoxyribonucleic acid synthesis). A previous publication[3] dealt with the effects of radiations on the pre-synthetic period (G_1 period); the present report is concerned with effects on the period of synthesis of deoxyribonucleic acid (S period) itself.

Human bone-marrow cell suspensions obtained by sternal puncture were used. The methods of culturing such suspensions *in vitro*, of high-resolution autoradiography, and planchette counting have been described previously[3-5]. 300-kV. radiation was employed (HVL 2 mm. copper) with a dose-rate to the cells of 480 rads/min. Sodium formate labelled with carbon-14 (4 μc./μM) was added to the medium 1·25 μc./ml. as deoxyribonucleic acid label.

As previously mentioned[3], in human bone-marrow cells *in vitro* the duration of the period of synthesis of deoxyribonucleic acid is about 12 hr. In short-term (1½–4 hr.) incubation with formate labelled with carbon-14 more than 85 per cent of the cells which collect sufficient amount of label for a visible autoradiograph will have been in the synthetic period at 0 hr. Irradiation of such short-term cultures therefore measures the effect of radiations on the period of synthesis of deoxyribonucleic acid directly; this could be an inhibition of synthesis as well as a reduction in the rate of synthesis.

The relative biological efficiency of α-particles compared with X-radiation was measured by dissolving radon gas in the medium in which the cells were suspended. For such irradiations, small (7-ml.) culture bottles were used for cutting down the air space above the fluid. Within 30 min. 500–5,000 rads could be delivered by the α-particles to the cells; the radon gas was then removed by aeration and the cell suspensions were transferred to the regular culture bottles for incubation with formate labelled with carbon-14.

Synthesis of deoxyribonucleic acid was measured by the average grain count per labelled cell, or by the total radioactivity in 12 × 10^6 cells. Previous experiments have shown that in such short-term incubations with the doses of radiation employed, the proportion of labelled cells does not change; it is the grain count over the labelled cells, that is, the amount of deoxyribonucleic acid synthesized per cell during the time of incubation, which is depressed by radiation.

The time relationship of depression of synthesis of deoxyribonucleic acid produced by a dose of 2,000 rads X-rays is shown in Fig. 1. It indicates that: (*a*) after 2,000 rads synthesis of deoxyribonucleic acid in the cells proceeds at about half the normal rate; (*b*) extrapolation of the slope of the reduced rate of synthesis intersects the control line at about 30 min., below which time presumably no depression is measurable.

The dose–response curve for X-rays on synthesis of deoxyribonucleic acid during a 4-hr. incubation period is shown in Fig. 2. (*a*) The pooled results of fifteen experiments (●——●) suggest that the curve of depression of rate of synthesis of deoxyribonucleic acid with increasing dose can be analysed in terms of two exponential components, one with a steep slope (S_1) and the other with a shallow slope (S_2). (*b*) The dose for 63 per cent depression for the S_1 component is about 500 rads, that for the S_2 component 13,000 rads. (*c*) In any single experiment a dose of 2,000 rads may produce as little as 30 per cent or as much as 65 per cent depression (mean 50 per cent), but the slope of the S_2 component remains the same (—). (*d*) Extrapolation of the mean S_2 slope intersects the scale at 40 per cent depression, but in different experiments it intersects at between 20 per cent or 60 per cent depression. (*e*) The relative biological efficiency for radon α-particles at 500 and 5,000 rads was found to be about 0·5.

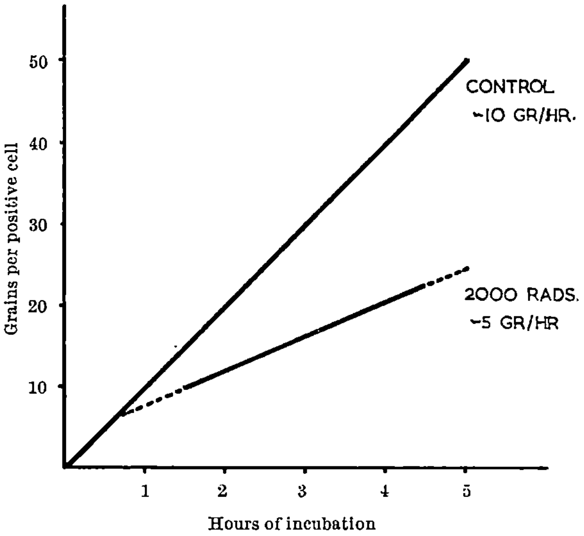

Fig. 1. Variation with time of depression of synthesis of deoxyribonucleic acid by a dose of 2,000 rads X-rays. Mean of four experiments

The experimental error of any single point on the above curves is scarcely greater than the black circles on the main curve.

It is emphasized that in these experiments practically all the cells investigated were in their period of synthesis of deoxyribonucleic acid (S period). The results, therefore, refer to effects of radiation during the period of synthesis of deoxyribonucleic acid, that is, as nearly as is possible at present, to the process of synthesis of deoxyribonucleic acid in the cell.

(1) The time relationship of depression of synthesis of deoxyribonucleic acid shows that up to 4½ hr. after a dose of 2,000 rads synthesis of deoxyribonucleic acid is not stopped, but proceeds at a reduced rate. The term 'rate' is defined here as the amount of deoxyribonucleic acid label collected per cell during unit time. It also shows that this decreased rate of synthesis does not become apparent until

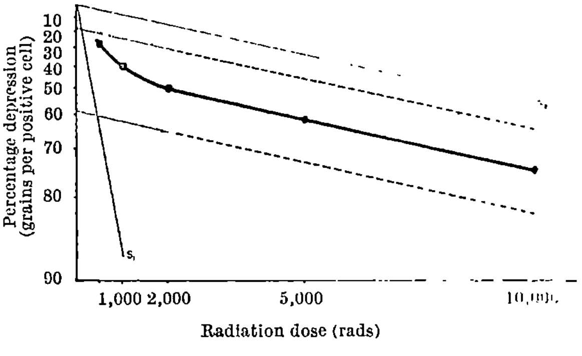

Fig. 2. Dose–response curve for X-rays on synthesis of deoxyribonucleic acid during a 4 hr. incubation period. ● -- ●, mean of fifteen experiments; ——, minimum and maximum curve (in single experiments)

some time (in our experiments probably about $\frac{3}{4}$–1 hr.) after irradiation.

(2) In view of the above, as the dose–response curve is the result of experiments with 4 hr. incubation with deoxyribonucleic acid label, it shows the depression with increasing dose of the *rate* of synthesis of deoxyribonucleic acid during a 4-hr. period.

In a 4-hr. incubation period 4-hr. 'worth' of cells would proceed from the pre-synthetic period (G_1 period) to the synthetic period (S period)—all data take this factor and the G_1 delay[3] into consideration.

(3) The dose–response curve can be analysed as two exponential components, the S_2 component giving a remarkably good straight line suggesting a single-hit type of mechanism.

The bone marrow being a heterogeneous population of cells, it was essential to determine whether the different cell types showed different sensitivities to radiation. This was not the case: pilot experiments had shown that early nucleated red cells and myelocytes show similar sensitivity in terms of radiation effect on the rate of synthesis of deoxyribonucleic acid.

Even in counting the myelocytes, one is not dealing with a pure clonal strain of cells, and therefore theoretically differences in radiosensitivity could be expected. However, in that case the dose–response curve would indicate two sharply different populations of myelocytes, one with a 37 per cent dose of 500 rads, the other of 13,000 rads. This sharp difference in the slopes of the components makes an explanation based on population differences very unlikely.

(4) A mechanism which results in decreased rate of synthesis of deoxyribonucleic acid per cell with increased dose of radiation (and not elimination of cells from synthesis of deoxyribonucleic acid) indicates that subcellular 'targets' are involved. Although the mechanism of damage is not yet clear, the exponential dose–response curve encourages one to consider a single-hit process, and to calculate the corresponding 'vulnerable volume' (a perhaps more fitting term than 'target', under our experimental conditions) from data given by Lea[6]. Thus, a relative biological efficiency of 0·5 between X-rays and radon α-rays leads to an individual volume of $4 \cdot 8 \times 10^{-8}$ μ^3 (ref. 6, Fig. 11), and a 63 per cent depression dose of 13,000 rads for X-rays would indicate 1,500 of these volumes per chromosome, a total of $7 \cdot 2 \times 10^{-5}$ μ^3 (ref. 6, Fig. 8*a*), corresponding to a total volume of $3 \cdot 3 \times 10^{-3}$ μ^3 per cell. Alternatively, these results can be considered to indicate a vulnerable volume in the form of a long filament, about 54 A. × 3·25μ per chromosome[6]. Even considering the very tentative nature of such calculations it seems clear that the dimensions are very much subcellular.

(5) The results are not sufficient to give a clear explanation as to the mechanism of the radiation effect on the process of synthesis of deoxyribonucleic acid, but based on them the following tentative hypothesis has been evolved.

The rate of synthesis of deoxyribonucleic acid in the bone-marrow cells (amount of deoxyribonucleic acid synthesized per cell per unit time) depends on two components, S_1 and S_2.

As to the nature of the S_2 component, we propose that it represents the integrity of the deoxyribonucleic acid template. Our calculations of the vulnerable volume for the S_2 component, tentative as they are, are compatible with such a concept. If, however, the nature of the radiation damage in S_2 is the breaking of the deoxyribonucleic acid double helix, then a dose of 10,000 rads should break only 0·1–0·5 per cent of the deoxyribonucleic acid molecules (mol. wt. 6×10^6 in a cell; Butler, J. A. V., personal communication). As Fig. 2 indicates a depression of at least 50 per cent due to the S_2 component alone at 10,000 rads, this may indicate that a larger functional unit is inactivated if a fraction of the deoxyribonucleic acid molecules in it is damaged—such a unit may be a part (or whole) of a chromosome. If enough parts of chromosomes (or whole chromosomes) are rendered incapable of synthesis of deoxyribonucleic acid, then the cell will synthesize: (*a*) less deoxyribonucleic acid per unit time; and (*b*) less than the full diploid amount of deoxyribonucleic acid per synthetic period.

As to the nature of the S_1 component, it may be part of the biochemical mechanism of precursor synthesis. At this stage it is not known whether the S_1 damage is destruction of an enzyme, or liberation of inhibitory substances, but it may well be a mechanism similar to that suggested by Ord and Stocken (previous communication). The delay in time of appearance of the S_1 damage may indicate destruction of an enzyme which produces some key compound. After destruction of the enzyme the cell would have to use up the compound made before destruction of the enzyme, before the lack of the compound becomes measurable. In different cells this time may be different, depending on the amount of compound available after the destruction of the enzyme. Apparently, in different cells the amount of the S_1 component may vary: a dose of 2,000 rads which destroys the S_1 component may result in only 30 per cent or as much as 60 per cent depression of the rate of synthesis of deoxyribonucleic acid. According to this concept, destruction of the S_1 component may slow down the rate of synthesis of deoxyribonucleic acid in the cell without necessarily preventing the synthesis of the full diploid amount of deoxyribonucleic acid. Experiments are in progress to elucidate the nature of these components.

(6) It has been known that in studying radiation effects on synthesis of deoxyribonucleic acid *in vivo*, changes in cell population or mitotic inhibition may obscure the picture. It was pointed out[3] that, even *in vitro*, interference with cell-cycle processes (elongation of the pre-synthetic period) have to be taken into account. It appears that even if all these are considered, the rate of synthesis of deoxyribonucleic acid in the cell depends on more than one factor. Until all these are elucidated one cannot interpret radiation effects in biochemical terms.

Electric Field Theory of Auroræ

From time to time theories of the aurora have been proposed which invoke locally developed electric fields as the mechanism causing acceleration of solar particles into the relatively low levels of the ionosphere at which visible aurora usually occurs. However, these theories have been concerned mainly with an explanation of the classical idealized magnetic storm, treating the auroral phenomena as a by-product, and not attempting any detailed explanation of auroral morphology. One notable exception is the recent work of Chamberlain[1], in which an attempt has been made to explain the luminosity-height characteristics of an auroral ray in terms of an electric field in the ionosphere. The purpose of this communication is to present a crude qualitative description of the development of a typical auroral display as a result of the growth of an electric field in the ionosphere.

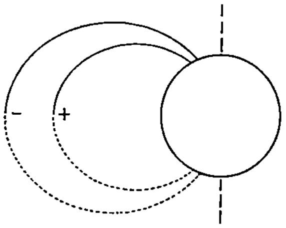

Fig. 1

Fig. 1 shows two lines of the geomagnetic field intersecting the Earth's surface in auroral-zone latitudes. Let us suppose that a potential difference is applied between these lines at their outermost extension as shown, without for the moment considering how this voltage is set up. The electrical conductivity of an ionized gas with an applied magnetic field is not isotropic[2], the conductivity transverse to the field lines being less than that along the field lines by a factor:

$$\frac{\nu^2}{(\omega_H^2 + \nu^2)}$$

where ν is the collisional frequency and ω_H is the radian gyrofrequency in the magnetic field. The values of ν and ω_H will be dependent on the type and charge of the particles under consideration, but we will restrict ourselves meanwhile to considering the electrons in the gas. At distances of the order of the outermost extent of the field lines, the collisional frequency is extremely small, so that the current flow will be strictly along the field lines, and the conductivity will be very large due to the long mean free path. As we penetrate the ionosphere, the conductivity transverse to the field lines will gradually increase since ν increases more rapidly than ω_H. The actual value of this transverse conductivity at any height will, however, also depend on the electron density at that height, and will vanish completely below the E-region, where the night-time electron density becomes zero.

The picture, then, is of a current flow along the field lines and across the ionosphere in a meridional direction over a finite range of heights. This idea of a discharge via the ionosphere is by no means new—the same mechanism was invoked by Martyn[3]; but no detailed consideration of its effects on auroral morphology was given.

It is reasonable to assume that the electric field at any point around this circuit will be dependent on the local conductivity, by analogy with Ohm's law. The situation is complicated by the fact that the effective conductivity at any point is itself dependent on the field, as has been pointed out by Chamberlain[1]. However, we can still say that the total potential drop will distribute itself around the circuit in such a way that the regions of low conductivity will experience a relatively high electric field.

This field will reach its highest value at the lowest point at which ionization exists, that is, at the bottom edge of the E-region in contact with either line of force. It is thought that the meridional field will be less than this because here the flow of current takes place over a very large area. If the total potential drop is now allowed to increase steadily, we shall start to see visible light first at E-region heights, corresponding to excitation of the air molecules. The appearance would be that of a homogeneous arc lying along a parallel of geomagnetic latitude. The important factor here is not the field alone, but the product of field and mean free path ($E\lambda$). By considering the energy distribution of electrons in an electric field, Chamberlain[1] has derived the expression:

$$J = kN(E\lambda e)^{2/3} \qquad (1)$$

for the current density, J. Here k is a constant, N is the electron density and e is the electronic charge. From this we obtain:

$$E\lambda = \frac{1}{e}\left(\frac{J}{kN}\right)^{3/2} \qquad (2)$$

Equation (2) shows us that as we travel up from the E-region into regions of increasing electron density, $E\lambda$ decreases, so that a relatively large drop in potential would be necessary to produce excitation. However, it is conceivable that at very great heights, N again becomes so small that $E\lambda$ can reach excitation proportions. Since the atmosphere probably contains a large proportion of hydrogen at these heights, we might see a glow of hydrogen emission which would appear to the south of the arc, due to the bending over of the field lines as shown in Fig. 1. This reasoning, of course, assumes that J is constant along the field line, which may be true to a sufficient degree of accuracy for our purposes.

If the potential continues to increase, the arc will start to extend vertically, until eventually the field in the meridional direction reaches a large enough magnitude to produce ionization along the horizontal portion of the path through the ionosphere. Once this happens, the total resistance of the 'circuit' decreases suddenly, leading to a large increase in density of current, coinciding with the appearance of light across large areas of the sky. At the same time, the conductivity of the horizontal portion of the circuit becomes greater in comparison with that of the vertical portion, so that more of the total potential drop appears across the vertical portion, causing the electrons to be accelerated more rapidly.

It is suggested that a process of this type might account for the auroral break-up phenomenon, and that the vertically accelerated electrons are the cause of the X-rays which have been reported as appearing when quiet arcs break up into active forms[4]. The display will continue until the voltage has been discharged.

It is interesting to note that during daytime, N is so much larger that this discharge would occur much more rapidly without the production of extra ionization, so that aurora would be expected to be a night-time phenomenon. The same reasoning might explain the summer minimum in auroral activity. To explain the equinoctial maximum, we must remember that there are, in fact, two 'circuits' in parallel, one in each hemisphere. During the northern winter, most of the discharge will occur through the more highly conducting southern ionosphere, and only near the equinoxes will the two conductivities become nearly equal. Another interesting consequence of this mechanism is that the detailed form which an auroral display takes might be expected to be dependent on the local ionospheric conditions existing before the display begins. This point could be fairly easily checked.

It must be said that the foregoing remarks in no way pretend to form a theory of aurora. They have been presented merely to direct attention to what may prove to be a useful line of thought. Many questions of auroral behaviour have been left unanswered, and it is hoped that a quantitative examination of the validity of the process, which is now under way, might provide some of the answers.

I am indebted to my colleagues at the Geophysical Institute, and especially to Dr. C. T. Elvey, for stimulating discussion of this material.

Health Hazards from Powerful Radio Transmissions

For many years radio-frequency heating has been used under controlled conditions for medical purposes. It is clear that radiation from a powerful transmitter might also cause heating of body tissues, and this, if excessive, would be harmful. While precautions have always been necessary to prevent this, the problem has recently become more important, since the powers and aerials now used are such that levels of field-strength considered to be dangerous can occur at some distance from the transmitter. In fact, this may be an important consideration in siting powerful transmitters.

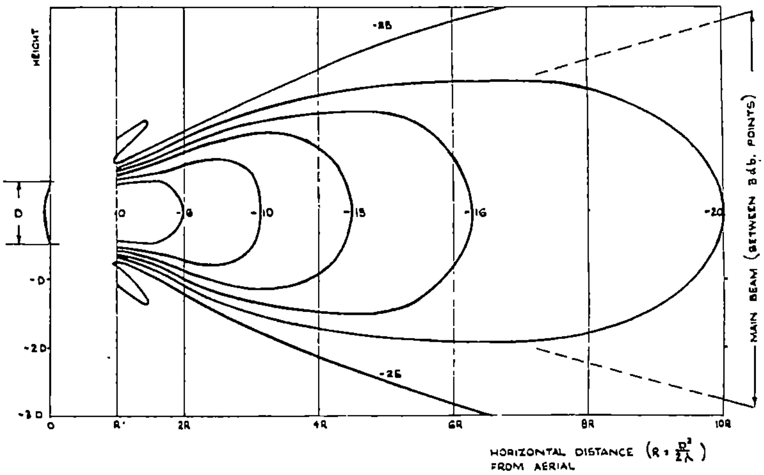

Fig. 1. Field-strength contours (in decibels) due to paraboloid of diameter D in free space

The level of field-strength which is dangerous was discussed by Schwan and Li[1]. They state that the maximum steady flux tolerated by the body is 30 mW./cm.^{2} for frequencies less than 500 Mc./s., 10 mW./cm.^{2} for frequencies between 1,000 Mc./s. and 3,000 Mc./s., and 20 mW./cm.^{2} for higher frequencies; for short exposures a much greater flux can be tolerated, for example, 300 mW./cm.^{2} for 1 min. It is of interest to predict, for particular powers and aerials, the positions at which the field will exceed the critical value.

Consider a simple aerial, a paraboloid fed by a horn; and assume that the gain of the horn is 8 db. (relative to an isotropic radiator), and the field at the edge of the reflector is 10 db. less than the field at the centre. The field outside the reflector will be less than this. It follows that, except in the region between the horn and the reflector, the direct field from the horn can be taken to be less than it would be if the horn were an isotropic radiator. This enables us to specify a 'danger distance' from the horn, for example, 3 m. for a horn radiating 10 kW. It is clear, therefore, that the danger area due to direct radiation from the feed is small.

This does not apply to the danger area due to the main field of the aerial. Fig. 1 shows the rough shape of the main field at distances between R and 10 R from the aerial, where R is the 'Rayleigh distance', $D^2/2\lambda$, D being the diameter of the aerial. The contours are drawn relative to the 'maximum power flux'. This is taken to be the power flux on the axis at the Rayleigh distance. It is approximately equal to $2{\cdot}3P/D^2$, where P is the power. The power flux will in fact exceed this by up to $3\frac{1}{2}$ db. at some positions within the Rayleigh distance[2].

If P is 20 kW., D is 10 m., and λ is 35 cm. (reasonable parameters for a tropospheric scatter system), then the maximum power flux is 46 mW./cm.^{2}, and R is 141 m. If we add a factor of safety of 4 to Schwan and Li's figure of 10 mW./cm.^{2}, then the safe contour is 13 db. less. If the mean height of the aerial is 10 m. above the ground and the ground is level, then the whole of the ground between 270 m. and 620 m. (say half a mile) in front of the aerial is within the danger zone, since the flux exceeds the safe flux at heights below 2 m. This would normally by unsatisfactory. It can be remedied either by increasing the mean height of the aerial to 14 m.

or by tilting the aerial upwards by 0·45°, that is, about one-fifth of a beam-width. Such an aerial could therefore safely be placed on a cliff overlooking the sea, or with ground sloping away in front of it at an angle exceeding 0·45°.

The field at distances from the aerial less than the Rayleigh distance is largely confined within a cylinder the base of which is the reflector. The field below this cylinder is generally about the same as it is at the same height at the Rayleigh distance[2]. For example, for the aerial considered above (10-m. reflector, mean height 10 m., wave-length 35 cm.) the field at a height of 2 m. above the ground varies as one moves away from the aerial but is always more than 20 db. less than the 'maximum power flux' up to a distance of 200 m.; as one moves farther away, it increases to about 10 db. at 340 m., and then decreases continuously, reaching 14 db. at 680 m. and 20 db. at 1,380 m.

It is worth pointing out that the fields computed are those in free space. The ground will reflect radiation, the reflexion coefficient being dependent on wave-length, polarization, and the dielectric constant and roughness of the ground[3]. If the reflexion coefficient is -1 (horizontal polarization, smooth earth), then the field-strength at some points will be 6 db. greater than that in free space. This would account completely for the 'factor of safety' of 4 taken into account above.

An ionospheric scatter system on, say, 40 Mc./s., would not in general have such a large danger area, since the maximum power flux would be smaller and the allowable power flux would be greater. Radar systems will also have a smaller maximum power flux, and so are unlikely to be dangerous except near the axis of the beam. Even right in the beam, there will be no danger provided that the aerial is kept scanning. It might be worth while to point out that medium powers and small aerials can be dangerous; for example, 100 watts and 1 metre diameter gives a maximum flux of 23 mW./cm.^{2}, well above the tolerable limit; the Rayleigh distance is, however, quite small, being only 5 m. for a wave-length of 10 cm.

All these conclusions are subject to review in the light of new biological findings. The work of Schwan and Li[1] seems rather conjectural, but is the only solid basis available at present, apart from serious effects caused by much higher power densities[4]. It is clear that the adequate application of safety precautions would be much facilitated by a simple instrument which indicates whether or not a field of, say, 2 mW./cm.^{2} is being exceeded. It is also of importance for pulse radar to know whether a strong field, say, 3 kV./m., lasting for a microsecond or so, can do any harm to the body apart from its heating effect.

Bismuth–Tellurium Photo-voltaic *p–n* 'Sandwich' Layer

IT has been fairly well established[1,2] that bismuth telluride changes conductivity type[1,2] with the excess of tellurium over stoichiometric proportion between 1 and 2 atomic per cent[3]. It has been assumed that each excess Bi(Te) atom replacing the Te(Bi) atom in the single crystal of Bi_2Te_3 behaves as an ionized acceptor (donor)[1-3].

It seemed to me that if the conductivity type of a layer of semiconductor, approximately 1μ thick, evaporated on to the surface of a plate of insulating material would change from *p* (or *n*) to *n* (or *p*) in the direction perpendicular to the plate surface, it would possess the photo-voltaic property. An attempt to process such a layer was successful. I then reasoned in the reverse direction. Both the fact that the layer has shown the photo-voltaic property and the method of its preparation have suggested that the layer is of a 'sandwich', *p–n* barrier type.

A layer of bismuth was evaporated *in vacuo* on to the surface of a glass plate 8 cm. × 2 cm., covering little more than half of its length. Then a layer of tellurium was evaporated on to the uncovered portion of the plate overlapping the end section of the bismuth film in the middle area of the plate. Thus, the central portion was a 'sandwich' type Bi–Te layer of the area of $\frac{1}{4}$ cm. × 2 cm., while the remaining bismuth and tellurium portions served as leads which enabled the connexion of the 'sandwich' layer in series with a galvanometer and eventually with a battery.

The layer was then heated *in vacuo* up to a temperature of about 150–200° C. for a few minutes. After removing it from the evaporator, the layer showed the following properties in atmospheric air. Its dark resistance was about 7,000 ohms at room temperature. Under an intensity of illumination of 25×10^{-5} lumens/mm.^{2} given by a tungsten lamp it decreased by about 15–20 per cent. The photo e.m.f. generated by the same radiation intensity amounted to about 50 millivolts. The bismuth electrode acquired positive potential on illumination in respect to the tellurium electrode. The response time was of the order of a few msec., proving the effect to be photo-electric.

Tentatively, these effects could be accounted for in the following way. As soon as crystallites of bismuth in the 'sandwich' portion of the layer come in contact with those of tellurium, diffusion of the tellurium (bismuth) atoms, enhanced by elevated temperature, into the bismuth (tellurium) crystallites occurs. It is presumed that one, or both, of two things may then happen: either tellurium (bismuth) crystallites with bismuth (tellurium) wrong site atoms, acting as acceptors (donors), or bismuth (tellurium) rich bismuth telluride (Bi_2Te_3) crystallites are formed, in the latter case with (0001) planes parallel to the glass plate surface.

In both cases *p–n* barriers would be formed, with the *p*-type material on the side of the bismuth electrode, and the *n*-type material on the side of the tellurium electrode. Electron (hole) type conductivity in the planes parallel to the surface of the plate glass may also occur in the bismuth (tellurium) portion of the sandwich layer. Photo-conductive layers of Bi_2Te_3 have been made by other investigators[4-5], but no details have been revealed.

The above method could perhaps be applied to other compounds characterized by low temperature of dissociation and considerable difference in the boiling temperatures of the elements (constituting elements belonging to groups occurring near each other in the periodic table of elements—narrow forbidden bands). To such compounds the 'evaporation method' applicable to compounds such as PbSe, PbTe, CdS[6,7] which do not dissociate during the evaporation (constituting elements belonging to groups occurring far from each other—wide forbidden bands) cannot be applied.

The method described seems to be promising in processing layers consisting of elements which obey the (8–*N*) rule in forming single crystals, and the behaviour of which can be explained in terms of Brillouin zones.

Evidence of Lattice Defects preceding Oriented Transformations during the Heat Treatment of Kaolinite

RECENTLY, Brindley and Nakahira[1] have expressed their belief in the existence of a defect silicon-spinel phase preceding the transformation into mullite of kaolinite. This view has also been endorsed by Steadman and Youell[2]. Brindley and Nakahira[1] have obtained evidence that the spinel phase has a high degree of orientation with respect to the original kaolinite crystal. Oriented transformations of this type have been observed by Bernal *et al.*[3] and by Steadman and Youell[2]. It may be mentioned here that I also observed oriented transformation of kaolinite into mullite during its heat treatment, the (002) plane of kaolinite being converted into the (231) plane of mullite[4]. The aim of this communication is to present experimental evidence for the existence of disordered phases preceding the formation of mullite during the heat treatment of kaolinite.

A sample of kaolinite from Singhbhum, India, was tested by the differential thermal analysis method. This resulted in two prominent endothermal peaks at 140° C. and 550° C. each and a prominent exothermal peak at 1,000° C. This is in conformity with the observations of Spiel, Berkelheimer, Pask and Davies[5]; Ross and Kerr[6]; and Grim and Bradley[7]; and showed that dehydration started at 140° C., was almost completed at 550° C. and a new phase, the mullite, appeared at 1,000° C. X-ray diffraction powder photographs of kaolinite were taken after its heat treatment to 510° C., 692° C. and 930° C., that is just before and after dehydration of kaolinite was mostly complete and during the formation of Brindley's spinel phase. The line profiles of the various reflexions were studied with the help of a Hilger non-recording microphotometer. From the observed line profiles the effects of particle-size broadening were eliminated, and the pure diffraction line profiles were recovered by applying the method due to Stokes. It is observed that pure diffraction line profiles of reflexions corresponding to the (002), (113), (131), (060), (331), (106) and (033) planes of kaolinite are asymmetrical and that the asymmetry of the curves increase with temperature. This means, according to Hendricks and Teller[8] and Wilson[9], that there are defects in the interlayer distances in those directions and that the disorder increases with temperature. Now these are the planes which ultimately[4] become converted into the (231), (422), (822), (0,12,0) and (444) planes of mullite. (Indexing of the mullite planes has been carried out according to the lattice parameters proposed by Gillery[10].) Thus it becomes apparent that the oriented transformation of kaolinite into mullite is preceded by lattice disorders which increase with temperature until the formation of the new phase starts.

A detailed account of the work will be published shortly.

A Method of studying the Variation with Temperature of Ultrasonic Absorption in Liquids

THE study of the temperature coefficient of ultrasonic absorption in liquids is of fundamental importance for an understanding of the particular molecular mechanism responsible for the phenomena observed. The dependence of absorption in liquids on temperature has been studied by a number of workers by taking measurements of absorption at different temperatures by the pulse method[1] and by the interferometer method[2].

The present communication describes a simple method of measuring the temperature coefficient of absorption using a fixed-path double crystal interferometer with the liquid under study enclosed between identical sender and receiving crystals. The sender crystal is excited at its fundamental by the radio-frequency voltage output from a crystal oscillator and power amplifier, and the voltage across the receiving crystal is measured by a sensitive valve voltmeter. As the liquid in the ultrasonic cell is heated gradually the deflexion in the valve voltme is found to change continuously, giving sharp max at those temperatures at which a stationary wa

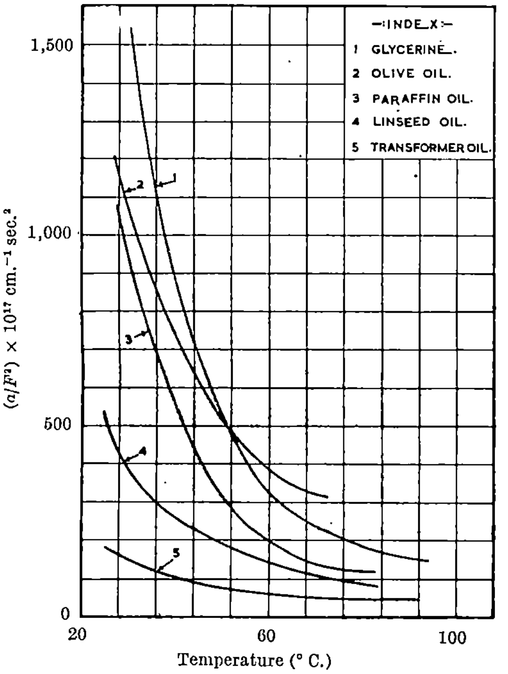

Fig. 1

formed in the liquid column. Following the treatment of Musa[3], it can easily be shown that these maxima occur at those temperatures satisfying the relation :

$$L = (2n + 1)\lambda/4 \qquad (1)$$

where L is the length of the liquid column and λ is the wave-length of the ultrasonic wave. The expression for the voltage V across the receiving crystal can be written in the form :

$$V_m = K/\sinh(\alpha L + \beta) \qquad (2)$$

where α is absorption per unit length and K is a constant. For highly viscous liquids, the value of the parameter β can be safely assumed to be small compared with αL, so that it can be neglected. Equation (2) can easily be utilized for the calculation of α at various temperatures provided K is evaluated by assuming a known value of α at one temperature determined by a standard method. By measuring the voltages across the receiving crystal at various temperatures at which maxima are observed and using equation (2) the absorption coefficient α is calculated at several temperatures and a graph can be drawn showing the variation of α with temperature. The method has been applied to some common viscous liquids and the results are shown in Fig. 1. The results for olive oil, glycerine and linseed oil are in good agreement with those of Verma[4] and Hunter[5]. It will be noticed that in almost all these oils the absorption coefficient falls off rapidly in a more or less exponential manner with increase of temperature.

The method has the advantage that there are no movable parts, and the equipment is quite simple. The accuracy of the determination of the variation of α, which is entirely dependent on the indicating voltmeter and the device measuring temperature, is found to be better than 5 per cent. The absolute accuracy of α depends on the accuracy of the value of α assumed or measured at one temperature. The method has the advantage that, with the same apparatus, the temperature coefficients of both ultrasonic velocity and absorption can be determined simultaneously using the same set of readings. It has been possible at present to apply this method only for the study of temperature effect on absorption in highly absorbing liquids having large temperature coefficients. However, the method can readily be modified for application to other liquids.

We wish to thank the Council of Scientific and Industrial Research for financial assistance for this project.

Diffraction of Light by Ultrasonic Waves, Oblique Incidence and Sound Intensity

THE experimental results reported in a previous communication[1] confirm the existence of several maxima for the second- and the third-order diffraction lines at oblique incidence and at low sound intensities, when the sound wave-length is small as expected by the closed intensity expressions of Aggarwal[2]. We have now observed for this small sound wave-length that, when the sound intensity is slowly increased, the number of these maxima diminishes. Further, the emphasis appears to shift towards the first Bragg angle, instead of the diffraction order attaining the maximum intensity at its respective Bragg reflexion angle. The secondary maxima for the second- and third-order diffraction lines at the Bragg angles corresponding to the higher orders slowly disappear, until the maximum intensity occurs only at the Bragg angle corresponding to the first order.

The experimental procedure was the same as that described earlier. Fig. 1 gives the results for the second order of the diffraction pattern on one side in terms of the Bragg angle at three different sound intensities. Here $\alpha/2$ is the reflexion maximum for the first order.

The graph shows that the second order attains three peaks at $\alpha/2$, α and $3\alpha/2$ at the lowest sound intensity (radio-frequency volts on the crystal: 22) which diminish to two at $\alpha/2$ and α with the increase in the sound intensity (radio-frequency volts : 54)

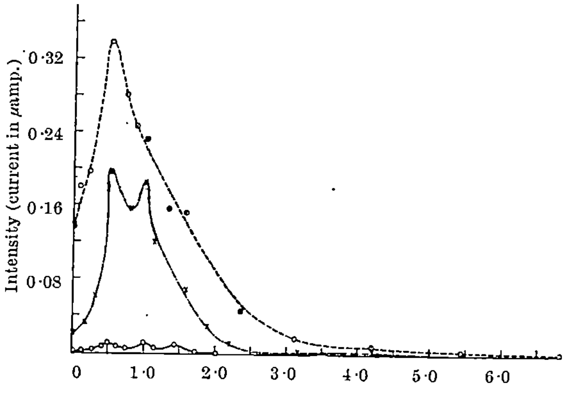

Fig. 1. Radio-frequency voltage : ○, 22 V. ; ×, 54 V. ; ○, 86 V.

and to only one at $\alpha/2$ with the further increase in the sound intensity (radio-frequency volts: 86). The pattern for the third order, which is not reproduced here, follows a similar trend; while that for the first order attained only one maximum at $\alpha/2$ irrespective of the sound intensity.

This phenomenon observed by us cannot be explained completely by any of the existing theories[3]. Aggarwal's closed intensity expressions become less accurate at higher sound intensities. However, from the series solution extended by Aggarwal[2], one sees that the variation in the intensity of a particular order is more pronounced for lower sound intensity. Thus the peaks decrease in number with the increase in the sound intensity. The results can only be qualitatively visualized on the basis of multiple diffraction. When the diffraction pattern contains many orders, the intensity of the lower order lines is the resultant of the contribution and redistribution from and to the lower as well as higher orders, while the contribution to the intensity of the highest order comes only from the lower orders. Therefore the variation in the intensity of a particular order will be more pronounced only when that particular order is the highest order in the pattern, or in other words, when the sound intensity is low.

The results can be explained mathematically only if one is able to obtain closed intensity expressions by considering the situation that all the orders exist simultaneously. Because of the mathematical difficulties in obtaining such a solution, a physical conception only is suggested at this stage.

Continuous-Flow Method for the Study of Microbiological Processes in Soil Samples

The existing means of studying microbiological processes in soil samples are derived from the classical methods of microbiological cultivation. They are based on the principle of a single enrichment of the soil with the appropriate substrate. The processes occurring there can be expressed by a curve characteristic of microbiological processes in closed systems. Even if these methods have produced some valuable results they have certain disadvantages, for example, the usually high initial substrate concentration and the fact that the exhaustion of the substrate causes the termination of the cycle. The first disadvantage of these classical methods of soil microbiology can be removed by the percolation technique[1,2], which makes it possible to supply the soil sample at a considerably lower concentration than required for batch cultures. But even in this case the substrate concentration undergoes changes in the course of the experiment and is exhausted in the end.

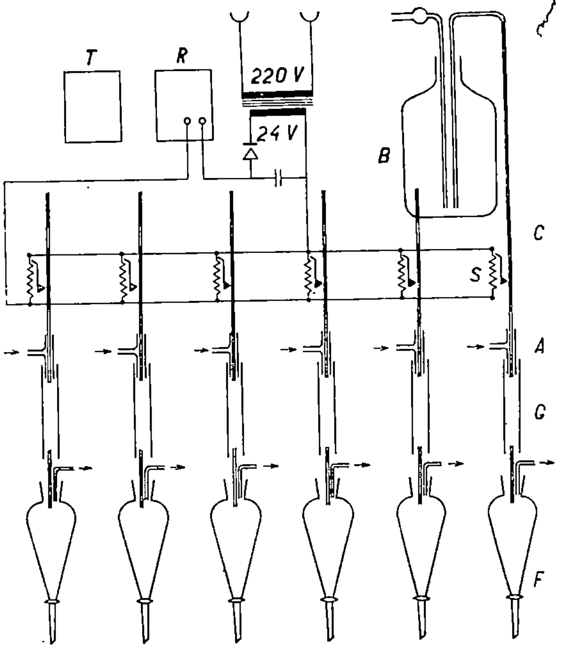

Fig. 1. A schematic representation of the apparatus for the continuous-flow method for the study of microbiological processes in soil samples

We have devised a method which makes it possible to introduce into the soil continually any desired amount of substrate the transformation of which is studied. Unlike in the percolation technique the solution passes through the soil not to return any more into circulation. It is basically an application of the continuous-flow method of culture of micro-organisms to the study of microbiological processes in the soil[3–6].

We have used an apparatus (Fig. 1) consisting of six cultivation units and a feeding mechanism. The stock solution inflow is regulated by electromagnetic screws[7] *S*, closing the rubber tubing through which the liquid passes from the stock bottle *B* to the growth tube *G*. The screws are controlled by a time switch *T* and by a slow-down relay *R*, which makes it possible to change the period of opened tubing between 0·5 and 2 sec.; the intervals between the individual impulses causing the screw to be released can vary between 15 sec. and 5 min. This mechanism ensures a constant flow and permits regulation of its rate. Capillary tubing *C* included in the circuit increases the regularity of amount of liquid passed in.

The cultivation unit is fundamentally identical with the percolation apparatus described by Audus[8] adapted for continuous flow. The soil sample is placed in a glass tube *G* closed at both ends with rubber stoppers. At the upper end of the cultivation tube the rubber stopper holds a wider glass tube with a side-arm *A* for passing in air and with a thin glass or capillary tube for passing in the nutrient medium which is connected with the stock bottle. After passing through the soil, the solution is collected in a separation funnel *F*. The stopper closing the separation funnel is provided with three holes, for the connecting tube from the cultivation flask, for an outlet to the pump and for a tube with a stopcock filled with an absorbent for the absorption of carbon dioxide; it serves also for passing air into the separation funnel when the collected solution is being removed.

The passage of the solution and the aeration of the soil are ensured by a constant suction similar to that in Audus's apparatus[8]. The introduced air is purified by removing carbon dioxide, and after passing through the soil it is introduced into the absorption flask with alkali; there the amount of carbon dioxide produced is estimated. The rate of air passing through is regulated by needle valves.

We have used this apparatus for studying nitrification and transformation of glucose in soil samples. When a glucose solution is passed through, the decrease in glucose concentration can be estimated as well as the production of carbon dioxide and the formation of volatile acids. We found that the formation of carbon dioxide and the volatile acids (related to the amount of glucose utilized) by the soil microflora is lower in the presence of nitrate than when a glucose solution containing no source of nitrogen is used. Only acetic acid could be detected by means of paper chromatography. The results show that under certain conditions an equilibrium state is established in the soil.

The method has principles in common with the method of heterogeneous continuous-flow cultivation of micro-organisms using a solid carrier. Similarly, as with continuous cultivations, it is possible also in our case to supply the soil continually with substrate at a considerably lower concentration than with other current methods. However, it is possible to prevent the exhaustion of the substrate and to ensure a sufficient amount of nutrients in the soil. Thus the soil population can be maintained at a certain level determined by the rate of flow and by the concentration of essential nutrients. As the controlling growth factor, an energy source, a nitrogen source and the like can function. It is also possible to follow the transformation of various substrates one after the other and to influence the composition of the soil microbial association.

Detailed results are to be published elsewhere.

Thermal Annealing of Chemical Radiation Damage

AT present the only observations on the thermal annealing of chemical radiation damage appear to be some measurements on potassium nitrate reported in 1955[1]. These measurements did not include isothermal kinetic studies, nor do they appear to exclude some possible alternative explanations of the observations. We have made measurements on the isothermal annealing of radiolysed lead nitrate and subsidiary experiments which seem to exclude any alternative explanation of the results. The experiments were conducted on a sample of vacuum-dried lead nitrate crystals sieved to between 80 and 100 mesh. The crystals were irradiated to a dose of about 50 Mr. with 2 MeV. electrons from a Van de Graaff accelerator. A typical plot of the disappearance of the nitrite, produced by the irradiation, upon thermal annealing of the crystals is shown in Fig. 1.

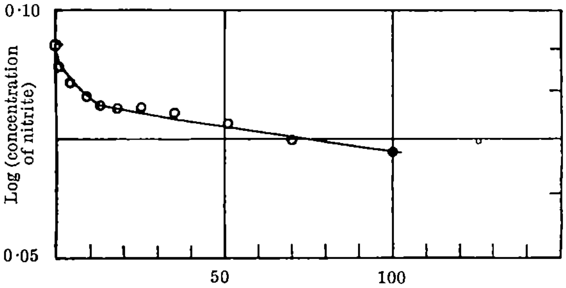

Fig. 1. Thermal annealing of irradiated lead nitrate

The possibility that the observed effect arose from aerial oxidation was excluded by showing that virtually the same annealing occurred whether the crystals were heated in air or *in vacuo*. Another possibility that the disappearance of the nitrite was due to thermal decomposition of the lead nitrite, to give lead oxide and oxides of nitrogen, was excluded by showing that in synthetic mixed crystals of lead nitrate and nitrite, prepared by crystallization from a solution of the nitrate and nitrite, the concentration of nitrite was unchanged after heating for 65 hr. at 150° C. *in vacuo*. It is concluded that the effects observed represent a true annealing of the chemical radiation damage. Similar experiments have shown that photolysed lead nitrate crystals can be annealed in the same way.

Such an effect is implied by the model for the radiolysis recently proposed by Cunningham and Heal[2], but the kinetic pattern of the recombination is more complex than the unimolecular recombination indicated by this model. A detailed account of the results and an analysis of the kinetic aspects will appear shortly.

Polymorphic Transitions in Anhydrous Sodium Sulphate

Kreidl and Simon have noted[1] that form V, the stable low-temperature form of sodium sulphate, was transformed, when in contact with water, directly and reversibly to the hexagonal high-temperature form I. This occurred at a temperature of about 238° C.

We have observed an irreversible change from form V to form I in the dry state at a temperature of only 176° C. (approximately). The observation was made in a high-temperature X-ray diffraction camera with the sample loosely packed in an open-ended quartz tube. Fig. 1 shows diffraction patterns recorded at temperatures of 161°, 176°, 180° C., and room temperature, in that order. These show respectively form V, a mixture of forms V and I, form I and form III.

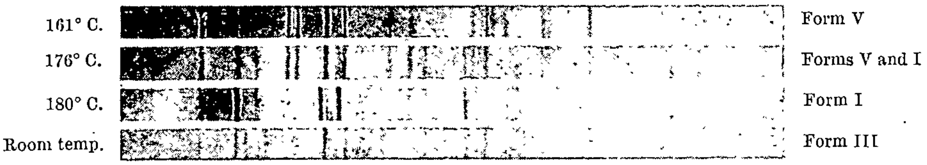

Fig. 1. X-ray diffraction patterns of anhydrous sodium sulphate. Sequence obtained during heating and cooling

From time to time in these laboratories we also have observed sodium sulphate to be present as form V after strong heating. In these cases, unlike Kreidl and Simon's experiment, cooling was not rapid nor was water likely to be present. We have not yet investigated the factors responsible for this change, which is contrary to the hitherto accepted behaviour of sodium sulphate.

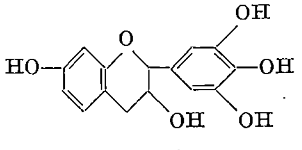
Black Wattle Catechin

Condensed tannins present in black wattle or commercial 'mimosa' extracts from the bark of *Acacia mollissima* show absorption behaviour ($\lambda_{\text{max.}} = 203$ and 280 mμ) in the ultra-violet spectrum[1], which is typical of the natural catechins and flavan-3.4-diols[2] and also of their constituent phenols. Furthermore, the degradation products resulting from the fusion of the tannins with alkali under anhydrous conditions (mainly resorcinol and gallic acid, but also phloroglucinol and protocatechuic acid), and from alkaline permanganate oxidation of the methylated tannins, resemble those degradation products usually obtained by similar methods from flavans[3]. On such evidence and by analogy with Freudenberg and Maitland's[4] earlier concept of 'quebracho catechin', one of us previously[5] regarded the catechin structure, 3.7.3′.4′.5′-pentahydroxyflavan (I), as a possible prototype of many of the complex tannins present in black wattle extract.



(I)

Recently, by means of methods outlined by one of us[6], constituents *G*, *H* and A_2 of wattle tannins[6] have been isolated in pure crystalline form and shown to be catechins. These rank among some of the major catechin components of the extract.

Constituent *H*, $C_{14}H_{15}O_6$, melting point 205–7° C., $[\alpha]_D^{20} = -10 \cdot 7°$, $\lambda_{\text{max.}} = 203$ and 281 mμ, gives colour reactions and degradation products indicative of the presence of resorcinol and pyrogallol nuclei only. Assuming the substance to be a flavan, the probable presence of five hydroxyl groups could be deduced from its chromatographic behaviour. Methylation with diazomethane afforded an O-tetramethyl derivative, melting point 140–1° C., $[\alpha]_D^{20} = -21 \cdot 6°$, showing that four hydroxyl groups are phenolic. The remaining aliphatic hydroxyl could be acetylated affording a mono-acetyl tetramethoxyl derivative, melting point 73° C.

These constants are in excellent agreement with those obtained by Weinges[7] for (−)-robinetinidol of structure I (and its corresponding derivatives), which was isolated from the hydrogenation of (+)-7.3′.4′.5′-tetrahydroxyflavan-3.4-diol (*leuco*-robinetinidin). This (−)-robinetinidol and constituent *H* from black wattle tannins show identical infra-red absorption curves over the range 2·5–15μ, and migrate to identical positions on paper chromatograms in three different and selective solvent systems. Mixed melting points of the corresponding derivatives show no depression. The presence of an *epi*-modification (2.3-*cis* substituents) of robinetinidol in wattle extract is also suspected from chromatographic evidence.

This, therefore, represents the first recorded isolation of a catechin (flavan-3-ol) of the resorcinol series from natural sources. The isolation of (−)-robinetinidol (2.3-*trans* substituents) also suggests that (+)-robinetinidol might occur naturally, as recently found for the enantiomorphous pair (+)- and (−)-7.3′.4′-trihydroxyflavan-*cis*-3.4-diol[8], and in apparent contrast with the phloroglucinol series of catechins, for example, gallocatechin, catechin and afzelichin, where mainly (−)-*epi*- and (+)-forms occur in plants.

Constituents *G* and A_2 of wattle extract were previously identified as (+)-catechin and (+)-gallocatechin respectively by means of paper chromatography by one of us[9]. This tentative identification is confirmed by their isolation and comparison with the same compounds obtained from *Casuarina equisetifolia*[10].

Our sincere thanks are due to Dr. K. Weinges, and to Prof. Karl Freudenberg, of the Chemical Institute, University of Heidelberg, for advance information regarding (−)-robinetinidol and also for specimens of the synthetic compound and its derivatives; also to Dr. J. R. Nunn, of the National Chemical Research Laboratories, Council for Scientific and Industrial Research, Pretoria, for kindly performing the infra-red comparisons.

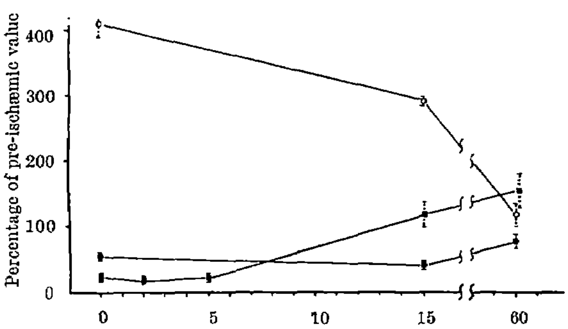
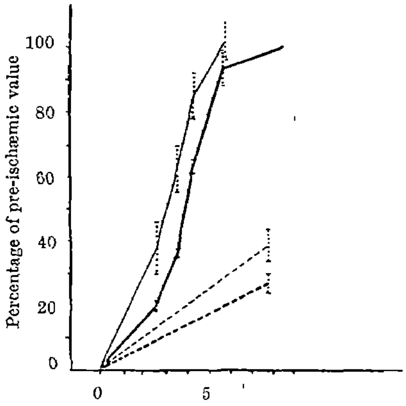
Evidence for a Relation between Creatine Phosphate Level and Polarity of the Cerebral Cortex

THE surface of the cerebral cortex in rats is 15–20 mV. positive against other electrically indifferent sites[1,2]. This steady potential can serve as an indicator of brain survival[3,4].

In the present study we attempted to characterize metabolic processes that might participate in maintaining normal cortical polarity. For this purpose the levels of some metabolites were determined in the rat brain during the various phases of steady potential changes caused by transitory brain ischæmia and following resuscitation. Rats anæsthetized with 'Dial' were used throughout. The polarity of the cerebral cortex was measured between an area damaged by thermocoagulation and the normal cortical surface using a chopper direct-current amplifier and cathode ray oscillograph. Ischæmia was induced by a modification of the method of Opitz and Thorn[5]. After exposing the trachea, the neck of the rat is compressed by a rubber band. Although some blood still goes to the head through the spinal and vertebral arteries under these conditions, there is a characteristic decrease in cortical polarity with a half-time roughly equal to that after decapitation. From the time of compression artificial respiration was applied through the free trachea so that cardiac activity remained normal. After 10 or 20 min. the rubber band was released and the return of polarity observed. In various phases of repolarization animals were killed by immersion in liquid nitrogen. Glycogen[6], glucose[7], lactic acid[8] and creatine phosphate[9] were determined in the hemispheres.



(a) Time after end of ischæmia (min.)



(b) Time after end of ischæmia (min.)

Fig. 1. Changes of (a) glycogen (●—●), glucose (■—■), lactic acid (○—○) and (b) creatine phosphate (thin line) and cortical polarity (thick line) after 10 min. (full lines) or 20 min. (interrupted lines) ischæmia. Vertical dotted lines indicate standard error of the mean

At the end of the 10 min. of ischæmia, when cortical polarity had disappeared almost completely, glycogen, in agreement with the literature, was down to 52 per cent, glucose to 26 per cent and creatine phosphate to unmeasurable values, while lactic acid had risen to 411 per cent of the original value. During resuscitation these changes gradually disappeared. Complete repolarization of the cerebral cortex was attained already after 8–9 min., when the above metabolites were still considerably decreased (Fig. 1a). Statistical analysis of 75 correlated pairs of values for repolarization and creatine phosphate-levels shows a close correlation ($r = 0{\cdot}61 \pm 0{\cdot}07$). Renewal of the original creatine phosphate-level precedes that of cortical polarity by a fraction of a minute (Fig. 1b). From the above and from what is known about cerebral cortical metabolism it seems reasonable to assume that a causal relationship exists between the level of creatine phosphate and cortical polarity. Experiments with 20-min. ischæmia show that this correlation is not accidental. Repolarization under such conditions is much slower, but the correlation between the cortical steady potential and creatine phosphate-level remains unchanged.

The inability of other authors[10–13] to find a direct relation between creatine phosphate or adenosine triphosphate decrease and disappearance of spontaneous electroencephalogram activity or evoked potentials during anoxia or ischæmia, may be explained by the fact that these forms of cerebral activity are due to synaptic organization of neurones and the corresponding specific metabolism of brain mediators. The cortical steady potential, on the other hand, is a result of potential differences between various parts of the cell membrane of the cortical neurones sustained by active transport of ions. Renewal of polarity during resuscitation is not dependent, therefore, on a return of glycogen, lactic acid and glucose to normal levels, but rather on a restoration of creatine phosphate, or possibly of other high-energy phosphates serving as a direct source of energy for active transport through the cell membranes.

Inward Movement of Calcium as a Link between Electrical and Mechanical Events in Contraction

Although there is every indication that the electrical events at the surface of cardiac and skeletal muscle fibres lead to the activation of the myofibrils within, there is as yet little definitive evidence as to the nature of the process linking these two events. Evidence showing that it is the depolarization of the fibre surface which is the electrical event responsible[1] has led many authors to suggest that the depolarization permits or promotes the entrance of a substance which then initiates the contraction. In particular, calcium ions have frequently been suggested as the substance responsible[2]. The recent demonstration by Hodgkin and Keynes[3] that there is an influx of calcium ions with each action potential in the squid giant axon has encouraged me to investigate the above hypothesis.

If there is an inward movement of calcium playing the part suggested above, it should be possible to eliminate the mechanical response of a skeletal muscle to electrical stimulation by soaking the muscle in a solution free of calcium. However, since this procedure makes skeletal muscle electrically inexcitable[4], another method was used. This consisted of studying the effect of soaking a skeletal muscle in a calcium-free solution for various periods of time on the contracture induced by a solution containing 25 m*M* potassium. The complicating effects on electrical excitability produced by changes in the concentration of calcium ions were eliminated by replacing 98 per cent of the sodium in the solutions with choline. All solutions contained 10^{-4} gm./cm.^{3} *d*-tubocurarine (Burroughs-Wellcome). The extensor digitis longis IV muscle of the frog was used because its small size (0·2–0·5 mm. diameter) allows rapid equilibration.

Typical responses produced by the excess potassium ions under the conditions specified are shown in Fig. 1*a* and *c*. Also shown are responses of the same muscle after treatment with the calcium-free solution. All mechanical recordings were produced under highly isometric conditions. After each response the muscle was placed in a solution containing the normal concentrations of potassium and calcium ions for 10–15 min. before another response was elicited. Each test, using calcium-free solutions, was preceded and followed by a control test. In these muscles the control responses remained essentially unaltered during 4–5 hr. of testing. The results obtained with two muscles are shown in Fig. 2. These represent the extremes obtained in about twenty muscles tested in this manner. Soaking in calcium-free solutions consistently inhibited the response, and, if continued for as long as 12 min., always completely eliminated the contracture induced by potassium ion. Similar results are obtained if an isotonic solution (123 m*M*) of potassium chloride is used to induce the contracture.

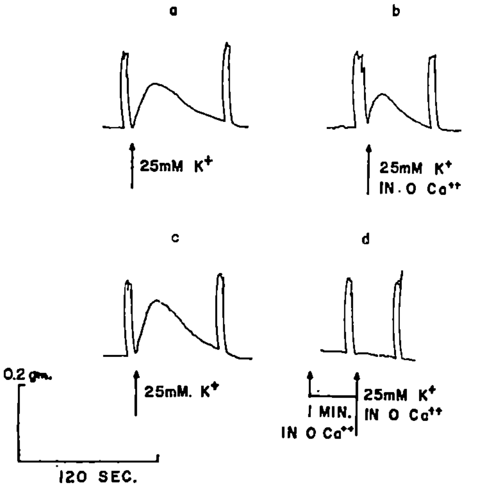

Fig. 1. Four successive contractures (*a*, *b*, *c*, *d*) produced during an experiment on a single muscle. *a* and *c* control responses. Large rectangular deflexions at start and end of contractures are artefacts produced by changing solutions in the bath

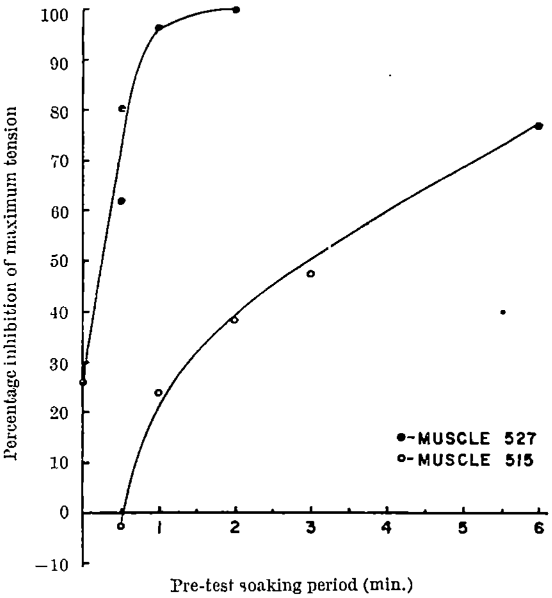

Fig. 2. Inhibition of the maximum isometric tension of the contracture induced by potassium ion due to pretreatment of the muscle with a calcium-free solution

That this change in the height of the contracture was independent of any change in the degree of depolarization produced by the excess potassium ion is shown in Fig. 3. The method of recording the depolarization is shown by the diagram in the lower part of the figure. The muscle was placed in a bath comprising two compartments which were isolated by a petroleum-jelly gap 8 mm. in length surrounding the muscle. The lines at the beginning of Fig. 3*A* and *B* indicate the potential difference between the two baths when they contained the same solution. The only change due to the calcium-free solution was a more rapid development of the depolarization induced by potassium ion. Maximum depolarization was the same in both records. In contrast, in most of the muscles tested, the maximum tension developed during the depolarization was 90–100 per cent inhibited by soaking for 5 min. in the calcium-free solution.

The above results demonstrate that soaking this skeletal muscle for short periods of time in a calcium-free solution inhibits the mechanical response of the muscle to a depolarization induced by potassium ion without changing the degree of depolarization. The short time necessary for this effect is in marked contrast to the long soaking periods for the removal of intracellular calcium[5], and strongly suggests that the effect is due to the removal of extracellular calcium. These results support the idea that ther is an inward movement of calcium ions when

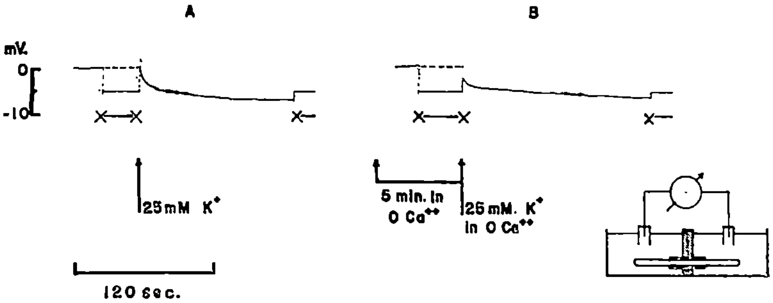

Fig. 3. Depolarizations produced by adding excess of potassium ions to the solution bathing a part of the muscle in one compartment of the bath. The recording instrument was turned off during the periods enclosed by the X marks (X—X) to permit the changing of the solution. The dashed lines are inked in continuations of the zero potential lines

muscle fibre is depolarized and that this calcium acts as a link between electrical and mechanical events in contraction.

In line with this work, Shanes and Bianchi have recently shown that there is an increased influx of calcium ions associated with action potentials and depolarizations induced by potassium ion in skeletal muscle (personal communication). Further details of this work, with evidence showing that the time course of this inhibition is determined by the rate at which calcium ions leave the extracellular space, will be published later elsewhere.

Influence of Cysteamine on the Teratogenic Action of X-radiation

IT has been shown by Bacq and his collaborators[1] that the administration of cysteamine (β-mercaptoethylamine) is an extremely effective method of protecting adult animals against X-radiation. The present series of experiments were carried out in order to determine whether the administration of cysteamine to pregnant animals immediately prior to exposure to X-radiation had any value in the prevention of X-ray induced malformations in their young.

Table 1

Group	No. of dams	No. of young	Average weight of fœtus (gm.)	No. of young with meningocœle	No. of young with cleft palate
1 Radiation only	30	155	0·39	44 (38·4 per cent)	149 (96·1 per cent)
2 Radiation and cysteamine	27	163	0·59	4 (2·4 per cent)	144 (82·2 per cent)

Fifty-seven female mice of the Strong *A* line were used in these experiments. Only brother–sister matings were used throughout the experiment and the onset of pregnancy was determined by the presence of a vaginal plug, the day on which the plug was detected being taken as day 1 of the pregnancy. Two groups of animals were formed. Animals in both groups 1 and 2 received 300 r. whole-body radiation on day 12 of pregnancy. Animals in group 2 received in addition, by intraperitoneal injection, 4 mgm. of β-mercaptoethylamine hydrochloride dissolved in 1 ml. of physiological saline, 2–5 min. before the onset of exposure to X-radiation. On day 18 of pregnancy all the animals were killed. The young were removed from the uterus, weighed and examined for the presence of deformities.

Deformities encountered included syndactyly, micromelia, anophthalmia, hydrocephalus, meningocœle and cleft palate. The incidence of the last two malformations is shown in Table 1. There was a markedly lower incidence of all deformities with the exception of cleft palate in the group which received cysteamine (group 2).

From the findings of these experiments it is concluded that the administration of cysteamine to the pregnant animal considerably mitigates the deleterious effects of X-radiation on the developing fœtus. The significantly higher average fœtal weight in group 2 suggests a parallel with the observation of Bacq *et al.*[2] that cysteamine protects the adult animal against the fall in weight which follows exposure to high doses of X-radiation. On day 12 of pregnancy the sensitivity of the developing mouse palate to 300 r. X-radiation is at its height[3], whereas the sensitivity of the brain and skull has passed beyond the most acute phase. It is significant in this regard to note that the administration of cysteamine in the quantities used in these experiments was considerably more effective in reducing the incidence of meningocœle than that of cleft palate.

Separation of Human Leucocytes from Blood

BECAUSE of the growing interest in the antigenic structure of human leucocytes, the need has arisen for a simple method of collecting pure suspensions of white cells, and for this reason the following method has been evolved.

Essentially, the technique comprises four stages. (1) The erythrocytes are encouraged to form rouleaux

Table 1. SHOWING THE SEPARATION OF LEUCOCYTES FROM WHOLE BLOOD

	Leucocytes				Erythrocytes			Leucocyte
	Volume (ml.)	Cells/mm.^{3}	Total cells × 10^6	Recovery (per cent)	Cells/mm.^{3}	Total cells × 10^6	Recovery (per cent)	Erythrocyte ratio
Whole blood	15	7,649 ± 79*	115·4	100	5,600,000 ± 79,700	84,000	100	0·0014
Supernatant (stage 1)	12	7,750 ± 150	93·0	81	7,000 ± 389	84	0·1	1·1
Sodium edetate suspension (stage 4)	5	4,562 ± 342	22·3	19·8	< 2·5	< 0·0125	< 0·000015	>1,800

* Standard error of mean.

by one of the published methods[1] and are allowed to sediment leaving the leucocytes in suspension. (2) The resulting suspension is placed as a shallow layer in a wide vessel to the bottom of which many of the leucocytes adhere. (3) The supernatant is discarded and the adherent cells washed free of erythrocytes with buffered saline. (4) The white cells are resuspended by gentle agitation in sodium edetate[2] ('Versene'; 'Sequestrene') dissolved in calcium- and magnesium-free buffer (solution *A* of Dulbecco and Vogt[3]).

Stage 1. Although we have used 'Dextraven' to sediment erythrocytes, it is probable that other methods would serve as well, provided that two considerations are borne in mind. First, the concentration of red cells must be reduced sufficiently to allow the leucocytes to become attached in stage 2 and, secondly, the concentration of white cells must be as high as possible. In practice, it has been found best to mix three volumes of blood treated with heparin with one volume of 6 per cent 'Dextraven' (Benger Laboratories, Ltd.) and to allow the mixture to stand in test-tubes for 1 hr. at room temperature. Suspensions obtained in this way contain 75–85 per cent of the leucocytes originally present with about an equal number of red cells. No advantage has been found in prolonging sedimentation or by sedimenting at other temperatures.

Stage 2. Much attention has been paid to the factors governing the attachment of leucocytes to surfaces. Although in early experiments white cells were allowed to adhere to glass which had been prepared for tissue culture, subsequent experience has shown that a greater proportion adhere to 'greasy' surfaces such as siliconed glass or 'vaspar' (equal parts of 'Vaseline' and paraffin wax). Provided that the latter surface is used, the proportion of leucocytes which adhere is unaffected by the concentration of plasma protein in the leucocyte suspension[5]. Using a layer only 2 mm. in depth we have found two factors to be of importance. First, the percentage of leucocytes that adhere to the surfaces during stage 2 varies directly with the concentration of those cells in the supernatant from stage 1. Secondly, the temperature is important because ten times as many intact cells were found at the end of stage 4 when leucocytes were allowed to become attached at 28° C. than when this step was carried out at 37° C. With the thin layers of fluid used, little advantage was noted when the period allowed for attachment was prolonged beyond 60 min.

Stage 3. The most important factor for obtaining leucocyte suspensions free from erythrocytes is thorough washing of the 'vaspar' surface; attached leucocytes seem able to withstand fairly vigorous shaking. In practice, three vigorous washes using each time at least the same volume of buffered saline as the original leucocyte suspension have been found to remove more than 99 per cent of the red cells. At this stage, examination of the adherent cells shows that these comprise 88 per cent polymorphonuclear cells, 6 per cent monocytes, 2 per cent eosinophils, 4 per cent small mononuclear cells thought to be degenerate polymorphonuclear cells and fewer than 0·1 per cent erythrocytes (Fig. 1). No lymphocytes were seen at this stage.

Stage 4. Virtually all the attached leucocytes may be removed from the 'vaspar' surface by gentle agitation with 1 : 10,000 sodium edetate for 15 min. at 37° C. Concentrations greater than this disrupt many of the cells, and lower concentrations fail to remove all the cells.

The technique at present used is as follows: A mixture of 3 parts of heparinized blood and one part of 6 per cent 'Dextraven' is placed in test-tubes and left at room temperature for 1 hr. Up to 20 ml. of the supernatant is then placed in a Roux bottle the sides of which have been coated with 'vaspar'. After leaving the bottle undisturbed on its side at 28° C. for an hour, the bottle is agitated and the fluid in it discarded. The adherent cells are thoroughly washed three times using 20 ml. buffer each time and 5 ml. 1 : 10,000 sodium edetate is run in and gently agitated for 15 min. at 37° C. The resulting suspension is then ready for use. The overall results of such a separation are given in Table 1, where it will be seen that about 20 per cent of the leucocytes originally present were recovered and the leucocyte–erythrocyte ratio rose from 0·0014 to more than 1,800; a purification of more than a millionfold.

Attempts have been made to assess the viability, the antigenicity and the purity of such white cell suspensions. Viability was assessed in three different ways. First, the proportion exhibiting dancing cytoplasmic granules[6] and the proportion thrusting

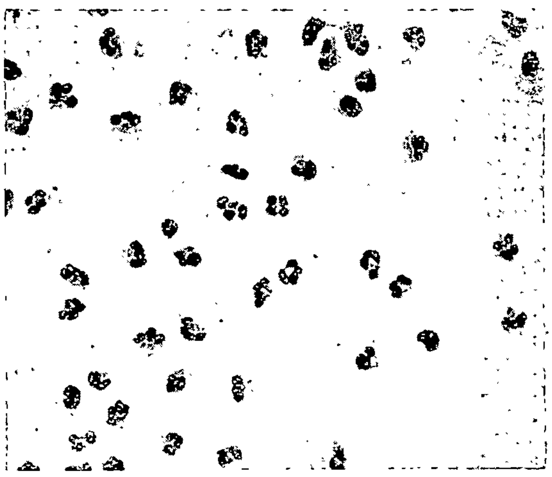

Fig. 1. Photomicrograph of a pure monolayer of leucocytes (stage 3). Leishman's stain. (× 280)

out pseudopodia, were determined by dark-field microscopy. Observation of 120 cells in the final suspension to which homologous serum had been added showed that 68 per cent possessed dancing granules and 64 per cent formed pseudopodia. Finally, phagocytosis of staphylococci by the leucocytes was studied. Although 80 per cent of the leucocytes appeared viable in these experiments there was difficulty in distinguishing between ingestion of the cocci and adherence to the surface of some of the cells. In fact, it seems possible that leucocytes remain sticky after viability is lost.

Antigenicity was shown by injecting a rabbit intravenously at weekly intervals with a million leucocytes/kgm. body-weight. It was found that serum taken ten days after the third injection and placed over a monolayer of leucocytes reduced the proportion of cells which exhibited dancing granules or formed pseudopodia. It also detached many cells from the glass and agglutinated them. None of these features was seen when serum taken from the same animal before immunization was used. White cell antibody was satisfactorily titrated by making a large number of replicate leucocyte monolayers of about a million cells each in slide cells (made by cementing 18-mm. stainless steel collars on to microscope slides with 'vaspar') and taking the separatory process up to the end of stage 3. Dilutions of serum were made in buffered saline, and 0·5 ml. of each was placed in a slide cell; these were incubated at 37° C. for 30 min. in a humid atmosphere. Each monolayer was then examined with a 2/3-in. objective. In control preparations the cells were still distributed as a monolayer attached to the glass while in immune serum detachment and agglutination were marked.

The method has the advantages that it is sensitive and simple to carry out, no human serum is present which might inhibit the antibody[1], the end-point is easy to determine and spontaneous clumping of cells does not interfere with the results. Using it we have found that serum taken before immunization had a titre less than 1 : 10, ten days after the third injection the titre was 1 : 1,280 and ten days after a further injection given at the sixth week the titre was 1 : 5,120. These three sera were titrated in parallel for red cell agglutinin by mixing the same dilutions with equal volumes of 2 per cent erythrocytes in buffered saline and reading microscopically after 30 min. The titres found were respectively $<1 : 10$, 1 : 20 and 1 : 160. Absorption of the last serum with erythrocytes reduced the red cell titre to less than 1 : 10 but left the white cell titre unaffected at 1 : 5,120. On the other hand, absorption with white cells reduced the white cell titre to 1 : 640 and the red cell titre to 1 : 40. These results suggest that this serum contained mostly white cell agglutinins and also antibodies specific for red cell and/or reacting with antigens shared by both cells[7]. Which of the last two possibilities were true might have been decided by mixed cell agglutination[8], but preliminary experiments have suggested that the phagocytic activity of leucocytes might give rise to mixed clumps of cells which would be mistaken for agglutinates.

It had been hoped to determine the purity of suspensions of white cells which were used as antigens by determining the nature of the antibodies produced. The preliminary studies mentioned above have failed to do this and the only criterion of purity that can be offered is that we have repeatedly obtained suspensions in which 2,000 to 3,000 leucocytes were consecutively counted without encountering a single erythrocyte and although they have not regularly been sought, platelets have not been found in final suspensions but have, on the contrary, been seen in large numbers in the suspension discarded during stage 3.

The method presented here of separating white cells from human blood combines a moderate yield with considerable purity and has the further advantages that spontaneous clumping does not occur and that cells remain viable and antigenic. Moreover, it may readily be adapted for titrating sera for leucocyte antibody. It is believed that the success of the method depends upon (*a*) avoidance of harsh procedures such as centrifuging and (*b*) the fact that the method selects only viable cells.

Effect of Temperature on the Multiplication of Foot-and-Mouth Disease Virus in Suspensions of Kidney Cells of the Pig

Recently, Lwoff and Lwoff[1] showed that the development of the virus of poliomyelitis in *KB* cell cultures (cell strain from a human epidermoid carcinoma—H. Eagle), while occurring 'normally' at 37° C., is at least partially blocked at 39° C., only about 0·2–0·4 per cent of the virus at 37° C. being produced. They found the blockage to be reversible and considered that it occurred in a "late stage of the vegetative phase".

No results of studies on the multiplication of the virus of foot-and-mouth disease growing in tissue culture at temperatures above 37° C. have been published. Cartwright, Pay and Henderson[2] recently published growth curves for 37° C.

In the present investigation this virus growing in pig kidney cells has been used exclusively. Pig kidney monolayers were prepared by Sellers's method[3]. Virus was titrated by the method of plaque counts[4], on pig kidney monolayers and also by 50 per cent end-point determination in baby mice inoculated intraperitoneally[5]; both methods giving similar results.

The virus strains used were pig kidney culture strains of either *M*.11 (Type *O*) or of *C* 997 (Type *C*).

Virus, usually not exceeding 0·4 plaque-forming units per cell, was placed on pig kidney monolayers. After 30 min. incubation at 37° C. the supernatant was removed and the cell sheet washed with saline buffered with phosphate and then treated with versene for 12–20 min. The resultant cell suspension was centrifuged at low speed, and after two washes in culture medium resuspended in this medium to give roughly 2×10^5 cells/ml. This suspension, after gassing with 5 per cent carbon dioxide in air, was incubated with continuous shaking in Carrel flasks in water-baths thermostatically controlled with a maximum fluctuation-range of 0·25 deg. C. Strict control of temperature has so far not been possible during the 75-min. preparation preceding this stage.

For each test two samples were withdrawn. The first was immediately diluted 1 : 10 in saline buffered with phosphate and served for 'whole-culture' titration. Three components make up this 'whole-culture' titre : unadsorbed infectious virus ; infected cells containing infectious virus not yet released into the supernatant ; and infected cells containing no infectious virus, but potentially capable of forming it if incubated further (eclipse phase). The second sample was immediately centrifuged and the supernatant titrated. Any infectivity detected was due to unadsorbed infectious virus, though occasionally a few infected cells may also have contributed. The cell pellet was disintegrated by the addition of a 1 per cent solution of sodium dodecyl sulphate. This detergent does not affect the infectivity of the virus yet disrupts the cells in a matter of seconds[6]. Suitable dilutions of the sample treated with sodium dodecyl sulphate were then titrated. Any infectivity found must be due to infectious virus which is 'cell associated', that is, infectious virus attached to or in the cells at the moment of treatment with the detergent. In certain cases where unadsorbed virus was present in the supernatant, a trace of this virus could also be present in the sample. No contribution is made by the disrupted eclipse-phase cells.

Virus multiplication was studied at temperatures of 35·0, 37·1, 39·6, 41·1, 41·7, 42·1, 42·6, 43·6 and 45·0° C. The period during which the infective virus titre increased, and the total increase in titre, was approximately the same at 35·0, 37·1 and 39·6° C. (in the same experiments). With increasing temperature, while the period of increase in titre seemed to be of about the same duration, the total increase in titre fell off rapidly : at 41·1° only about 50 per cent of the total at 39·6°, at 41·7° 5–10 per cent, at 42·1° less than 0·5 per cent, and at 42·6° and 43·6° C. no infectious virus at all was detected (Table 1). Thus the amount of infectious virus formed was reduced at temperatures between 41° and 42° C. and complete blocking of successful virus multiplication occurred at temperatures above 42·6° C. At 45° C. the infected cells, though surviving for 45 min., had all disappeared 90 min. later.

Table 1. VIRUS MULTIPLICATION AT TEMPERATURES ABOVE 39·6° C. Results from three experiments titrated on pig kidney monolayers. Titres given to the nearest 0·1 $\log_{10}$ unit per 0·4 ml. of suspension

wc, Whole-culture sample ; *sds*, sodium dodecyl sulphate-treated whole-culture sample.

* Transferred to 45·0° at 105 min.

As no infectivity was detected at any time in the samples treated with sodium dodecyl sulphate or in the supernatant at 42·6° and 43·6° C. (and also at all temperatures tested at 1½–2½ hr.) it follows that infectious virus amounted to less than 100 plaque-forming units (P.F.U.) per 4 ml. of suspension. Indeed, further experiments not included in the table showed that if infectious virus was present at all, it was less than 1 P.F.U. per 4 ml. Yet the same suspensions titrated as 'whole culture' contained more than 10,000 P.F.U. in the same volume. Thus comparisons of the curves for the 'whole-culture' with those for samples treated with the detergent (and with those for the supernatant) showed that at certain times in this system, and under these conditions of low multiplicity of original infection, all the detectable infectivity in a culture-sample resides in the *intact* cells which are presumed to contain virus in the eclipse phase ; that is in such a state that it cannot be extracted as infectious virus by means shown to be capable of extracting such virus. All virus appears to enter the eclipse phase soon after infection. The eclipse phase at 39·6° C. ended between 160 and 170 min. when virus infectivity first appeared in the sample treated with sodium dodecyl sulphate.

The blocking of virus multiplication at 42·6° and 43·6° C. is reversible and affects a late stage in virus growth : a late stage because transfer of infected cells incubated at 39·6°–42·6° C. up to 150 min. after initial infection, that is, within 10–20 min. from the normal end of the eclipse phase, completely blocked the production of infectious virus. Reversibility was demonstrated by transfer of the virus cell system from 42·6°—39·6° C. after varying periods of incubation at 42·6° C. Such transfer results in the formation of infectious virus. However, the virus cell system seems to be altered, for although infectious virus was demonstrated within 30 min. of retransfer to 39·6° C., the period of increase in virus titre after such transfer was about three times longer than the corresponding 'normal' period at 39·6° C. Clearly, the temperature block altered the balance of the virus – cell system in such a way that its effects persisted at least for some considerable time after removal of the blocking effect. There is also some indication that on retransfer to 39·6°, after several hours incubation at 42·6° C., less virus is produced per infected surviving cell.

Infected cells could be held for at least 36 hr. in the eclipse phase by incubation at 42·6–43·6° C. It is of interest in this connexion that the death-rate of eclipse-phase cells at 42·6° C. is about 90 per cent in 8 hr., while that of free virus in the supernatant fluid (*p*H 7·6) is more than 99·9 per cent.

It should be stressed that what is reported here refers only to virus – cell systems in which the multiplicity of infection per cell was of a low order. It was found that initial infection with greater multiplicities of virus led to the detection of some cell-associated infectious virus throughout the normal eclipse phase and also for many hours of the temperature-prolonged eclipse phase.

These observations indicate that by the combined use of the temperature blocking effect on an appropriate virus – cell system and sodium dodecyl sulphate for extraction of infectious virus it should be possible to obtain further information on virus absorption and penetration and on succeeding stages of the multiplication process of the virus of foot-and-mouth disease.

Effects of Potassium and Sodium Ions on the Resting and Action Potentials of the Giant Axon of the Cockroach

A knowledge of the fundamental properties of the insect nerve is very useful in studying the mode of action of insecticides, many of which are nerve poisons. In order to verify the validity of the sodium theory[1] in the cockroach giant axon[2], the effects on the resting and action potentials of varying the sodium and potassium concentrations in the bathing fluid were examined with intracellular micro-electrodes. A compensation circuit for improving high-frequency responses was employed in place of the simple cathode follower circuit used in our previous study[3]. The following mean values for the membrane potentials were obtained from axons immersed in modified Ringer's solution containing sodium ions at a concentration of 214 m*M*: resting potential 70·3 mV.; action potential 94·5 mV.; positive phase 3·4 mV.; maximum rate of rise of action potential 1,113 V./sec.; maximum rate of fall 382 V./sec.

Varying the external potassium concentration had a similar effect on the resting potential to that with other animals. Plotting the resting potentials against the logarithms of the external potassium concentrations resulted in a straight line in the higher concentration ranges. A decrease in the external sodium concentration had no appreciable effect on the resting potential, but it effectively depressed the action potential and eventually caused the axon to become inexcitable. The straight line for reversed potentials/log sodium concentrations diverged only slightly from the theoretically expected straight line having a slope of 59 mV. for a tenfold change in sodium concentration. Furthermore, when the axon came into contact with the solution deficient in sodium the rate of rise of the action potential was decreased more effectively than the rate of fall and the magnitude of the action potential. This behaviour of the cockroach axon in solutions of low sodium content is quite similar to that of the giant axon of the squid[4]. It can safely be said that the overall result constitutes strong evidence for the essential validity of the sodium theory in the giant axon of the cockroach.

Synaptic Transmission in the Cockroach

Although the synaptic transmission across the last abdominal ganglion of the cockroach has been studied by several workers[1–3], the knowledge obtained so far seems to be less complete than for synapses in vertebrate animals. In the present investigation electrical phenomena associated with the synaptic transmission across this ganglion were analysed with special reference to the nature of the synaptic transmitter. The cercal nerve–nerve cord preparation was isolated[4], and postsynaptic responses were led off from the origin of the connectives from the last abdominal ganglion.

A presynaptic volley set up excitatory postsynaptic potentials. When these reached a certain critical level, propagated action potentials were generated. Excitatory postsynaptic potentials could be observed more easily by employing pharmacological agents such as urethane and phenobarbital. These substances depressed the discharge of impulses from the ganglion cells, keeping the potentials observable.

An application of anticholinesterases such as eserine, tetraethyl pyrophosphate and parathion caused a marked increase and prolongation of the excitatory postsynaptic potentials with a prolonged after-discharge superimposed (Fig. 1,*A* and *B*). The excitatory potentials grew so markedly that a persistent ganglionic depolarization associated with a synaptic block was eventually produced. Repolarization associated with a recovery of synaptic transmission occurred after some time. Alternate depolarization and repolarization might occur without presynaptic stimulation. By employing urethane or phenobarbital it was clearly demonstrated that the anticholinesterases caused the ganglion to give a very prolonged excitatory postsynaptic potential with no discharges superimposed (Fig 1,*C*–*F*). Furthermore, it was found that the inactivation of cholinesterase after dosage with the anti-cholinesterases ran parallel with after-discharge.

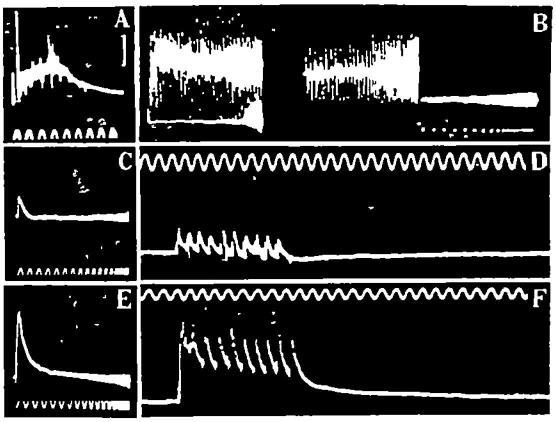

Fig. 1. Effects of eserine on postsynaptic responses. A voltage calibration of 0·5 mV. is applied to all records. Time markers are 50 c./s. except for *B*, which is 25 c./s. (*A*) Before treatment. A postsynaptic response evoked by a single presynaptic volley. A brief after-discharge. 14° C. (*B*) as in (*A*) but 47 min. after treatment with $5 \times 10^{-5} M$ eserine. A prolonged ganglionic depolarization superimposed with discharges. Time intervals between successive records are 15 sec. All records are arranged on the same base line. (*C*) An excitatory postsynaptic potential set up by a single presynaptic volley. Under $2 \times 10^{-2} M$ urethane 22° C. (*D*) as in (*C*) but by repetitive volleys. (*E*) as in (*C*), but 17 min. after treatment with $10^{-5} M$ eserine. An augmented and prolonged excitatory postsynaptic potential. (*F*) as in (*D*), but 41 min. after treatment with $10^{-5} M$ eserine. Augmented and prolonged excitatory postsynaptic potentials

When applied to the intact ganglion, the threshold concentration of acetylcholine for discharging impulses was as high as $10^{-2} M$. With the eserinized or desheathed ganglion, this was lowered to $10^{-3} M$. When the desheathed ganglion was eserinized, it was lowered to $10^{-4} M$; although it was still about one hundred times as high as for vertebrate ganglia and skeletal muscles.

With regard to transmitter substance in the last abdominal ganglion of the cockroach, three possible explanations are suggested on the ground of the present study.

(1) Acetylcholine may be a transmitter. However, since the susceptibility of subsynaptic membrane to acetylcholine is relatively low, it is necessary for acetylcholine to be stored and liberated in large amounts and for the cholinesterase to have a high activity. A high acetylcholine content and a high cholinesterase activity are known to be the case in the cord of the cockroach.

(2) Acetylcholine may be a transmitter. However, since a certain barrier around nerve cells prohibits the penetration of applied acetylcholine, the threshold concentration is high even after desheathing and eserinizing the ganglion.

(3) The synaptic transmitter may not be an acetylcholine-like substance. The prolongation of the excitatory postsynaptic potential following treatment with anticholinesterases suggests that the transmitter is a certain ester hydrolysed by cholinesterase.

In vitro Incorporation of Serine labelled with Carbon-14 into Mitochondrial Phospholipids

LITTLE is known about the biosynthesis of phosphatidyl serine. It has been suggested that the biosynthetic pathway of this phospholipid might be similar to that of phosphatidyl choline and phosphatidyl ethanolamine[1]. The present investigation describes the incorporation of uniformly labelled L-serine-^{14}C into the phospholipids of rat liver mitochondria and some of the co-factors required for this process.

The mitochondria were prepared by homogenizing rat livers in ten volumes of ice-cold 0·25 M sucrose containing $2 \times 10^{-3} M$ ethylenediamine tetraacetic acid, pH 7·4. Cell fractions were obtained by the usual fractional sedimentation[2]. The mitochondrial fraction was then washed once with the original volume of 0·25 M sucrose and finally suspended in 0·25 M sucrose (1 ml. per gm. wet weight of liver tissue). 1·5 ml. of mitochondrial suspension were incubated for 1 hr. at 37° with L-serine-^{14}C and various co-factors as outlined in Table 1. The reaction was stopped by the addition of 1/10 volume of 50 per cent trichloracetic acid. The precipitate was washed extensively with 5 per cent trichloracetic acid containing $2 \times 10^{-3} M$ D,L-serine. The extraction of the phospholipids from the trichloracetic acid precipitate, their separation from other lipids and pigments on silicic acid columns and the determination of their specific activity by means of liquid scintillation counting was carried out, as will be described elsewhere.

Table 1. Each system contained: 1·5 ml. mitochondrial suspension in 0·25 M sucrose, 0·25 ml. of 1·25 M sucrose, 0·4 ml. of 0·1 M phosphate buffer (pH 7·4), 0·2 ml. of 0·2 M magnesium chloride and 5 μM of L-serine (0·5 μc.). After the addition of co-factors as indicated below, the final volume was adjusted with distilled water to 3·0 ml. Time of incubation was 60 min.

Exp.	Co-factors added (μmoles)	Specific activity (disint./min./mgm. phosphate)
1	None*	77
	None†	335
	None	1,420
	ATP (10)	2,640
	ATP (10) + CTP (2·5)	1,380
	ATP (10) + CoASH (1)	7,220
	CMP (5)	12,900
2‡	None	1,290
	CMP (5)	5,040
	CMP (5) + ATP (10)	8,660
	CMP (5) + ATP (10) + CTP (2·5)	4,810
	CMP (5) + ATP (10) + CoASH (1)	25,050

* The reaction was stopped after 0 min. of incubation.

† In this experiment the mitochondrial suspension was boiled for 5 min. prior to incubation; the system contained 10 μmoles of ATP.

‡ In experiment 2 only 2 μmoles of L-serine were added (0·2 μc).

ATP, adenosine triphosphate; CTP, cytidine triphosphate; CMP, cytidine monophosphate; CoASH, reduced coenzyme A.

As can be seen in Table 1, cytidine monophosphate, adenosine triphosphate and reduced coenzyme A all increased the incorporation of L-serine into the mitochondrial phospholipids. Cytidine triphosphate, however, which is known to be required for the incorporation of phosphoryl choline or phosphoryl ethanolamine into the corresponding phospholipids[1], did not bring about an increase in the rate of incorporation. In fact, cytidine triphosphate suppressed the increased incorporation due to the addition of adenosine triphosphate (Exp. 1). The increased incorporation due to adenosine triphosphate plus cytidine monophosphate was partly inhibited by the addition of cytidine triphosphate (Exp. 2). Since the concentration of adenosine triphosphate was the same in both these experiments, it would seem that cytidine monophosphate and cytidine triphosphate are antagonistic. These results also show that the marked increase in the rate of incorporation due to cytidine monophosphate cannot be explained by transphorylation reactions forming cytidine triphosphate from cytidine monophosphate.

The combination of the co-factors cytidine monophosphate plus adenosine triphosphate plus reduced coenzyme A yielded an increased incorporation which was greater than the sum of those brought about by either cytidine monophosphate, or by adenosine triphosphate plus reduced coenzyme A. This result suggests that all three co-factors might act in a common pathway. Further experiments showed that the optimal concentration of cytidine monophosphate was found to be $3 \cdot 3 \times 10^{-3} M$, and that it could not be replaced by other 5′-mononucleotides. The optimal pH of the overall reaction was near 7·5. Magnesium ions ($12 \times 10^{-3} M$) increased the incorporation of L-serine in the presence of cytidine monophosphate plus adenosine triphosphate plus reduced coenzyme A, whereas calcium and fluoride ions were shown to be strongly inhibitory at the same concentration.

The radioactive phospholipid was identified by mild alkaline hydrolysis of the total phospholipids followed by separation of the resulting glycerylphosphoryl diesters on ion-exchange resins[3]. 95 per cent of the total radioactivity eluted from the resin column was found to be in the glycerylphosphoryl serine fraction, the remaining activity being in the glycerylphosphoryl ethanolamine fraction.

A more detailed report of this work will be published elsewhere.

Distribution of Tissue-Specific Antigens in Centrifugal Fractions of Rat Liver

The microsome fraction of rat liver parenchymatous cells has been shown to contain tissue-specific antigens[1,2]. These antigens are gradually lost from the cell during the course of carcinogenesis, the hepatoma cell being virtually devoid of them[3,4]. Thus they constitute an important difference between normal and cancer cells and offer a possibility for investigating the mechanism of de-differentiation that is linked with the property of uncontrolled growth. This communication is concerned with the identification of the subcellular structures which are involved in the immunological change.

Well-defined nuclear, mitochondrial and microsomal fractions were isolated from rat liver homogenates by the methods developed by de Duve[5]. Antimicrosomal sera were prepared in rabbits and made specific for the reaction with liver by heterologous absorption with kidney microsomes[4]. The quantitative precipitin method was used for the immunological tests.

The tissue-specific microsomal antigens in the nuclei and mitochondria were determined by measuring the antibody-binding capacity of these fractions. They were incubated with the antiserum, centrifuged, and the supernatant was tested for antibody by equivalence-point determination with microsomes as antigen. No measurable amount of antibody was removed from the specific serum by the mitochondrial fraction, and the antibody-binding capacity of the nuclear fraction was about 10 per cent that of the same amount of microsomes expressed in μgm. protein nitrogen. Thus the tissue-specific antigens of the microsomes appear to be confined to this fraction only, the residual activity of the nuclei probably being due to microsomal contamination.

Table 1. Microsomal Subfractions

	Particle size*	Protein content as percentage of that of untreated microsomes	Ribonucleic acid content as percentage of that of untreated microsomes	Ribonucleic acid content as percentage of ribonucleic acid plus protein	μgm. phospholipid phosphorus per mgm. protein nitrogen
Untreated microsomes	350	100	100	11·2	138
Fraction *M*	350	58	17	3·2	163
Fraction *RNP*	40	24	69	30	75
Fraction *S*	Supernatant	18	14	7·5	20

* Expressed in Svedberg units of the smallest particles sedimented under the conditions applied.

The microsomal material can be further fractionated into the constituents of the endoplasmic reticulum from which it is derived. Three fractions were obtained by suspending microsomes in a medium composed of 0·25 *M* sucrose, 0·08 *M* sodium citrate, and 0·01 *M* phosphate buffer *p*H 7·2 and subsequent differential centrifugation. Their characteristics are shown in Table 1. Fraction *M* represents the membranes of the endoplasmic reticulum, and contains most of the proteins and the lipids of the microsomes. Fraction *RNP* consists largely of the ribonucleoprotein particles of the endoplasmic reticulum. Membranous material is still present, however, as indicated by the lipid content. The final supernatant *S* includes proteins which are brought into solution by the citrate medium, presumably the contents of the microsomal vesicles.

Comparative equivalence-point determinations were performed with the three fractions, as well as with the untreated microsomes, against a fixed volume of tissue-specific antiserum. Material containing larger amounts of the particular antigen reached the equivalence point at comparatively lower concentrations. In these experiments it was found that the antigenic activity is highest in fraction *M*, less in untreated microsomes and still less in fraction *RNP*. Fraction *S* was completely inactive in the precipitin tests. Fig. 1 shows a comparative equivalence-point determination of fraction *M* and untreated microsomes, illustrating the difference in antibody-binding capacity of the two preparations which indicates that the material removed by the citrate extraction is antigenically largely inert.

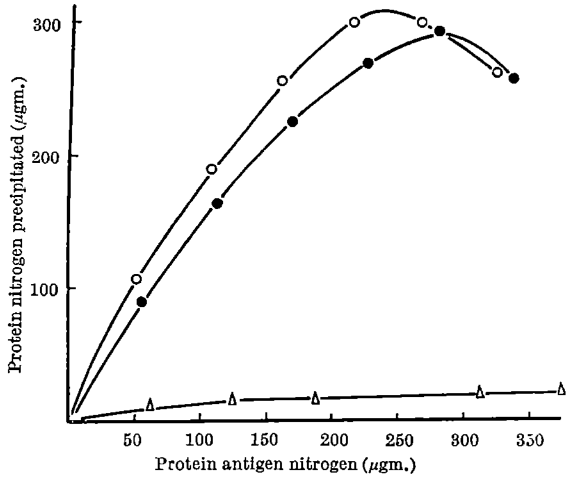

Fig. 1. ○—○, Fraction *M*; ●—●, untreated microsomes; △—△, kidney microsomes

There is a correlation between the antigenic activity of microsomal subfractions and their lipid content. If the latter is taken as a measure for the membranes of the endoplasmic reticulum this suggests that the tissue-specific antigens, probably lipoproteins, are located in these membranes.

In 48 hr. regenerating rat liver the ratio of ribonucleoprotein particles to membranes is changed by an increase of the amount of ribonucleoprotein particles[6,7]. Microsomes of such a tissue should then contain less of the specific antigens per protein weight as compared with microsomes from normal liver. This could be confirmed by equivalence-point determination.

This localization of tissue-specific substances which are known to disappear during carcinogenesis underlines the importance of organized cytoplasmic reticular structures for the state of differentiation[8]. Recent data on microsomes in cancer tissue can be correlated on the basis of the results presented above. Electron micrographs of sections from rat liver tumours induced with *p*-dimethylaminoazobenzene show only very few apparently randomly distributed membranous elements in the cytoplasm[8,9]. Glucose-6-phosphatase, an enzyme known to be bound to the endoplasmic reticulum membranes[10], is not present in the hepatoma[11]; furthermore, the phospholipid content of the microsomes is reduced[12].

On the other hand the amount of ribonucleoprotein particles is increased in the liver tumour[13]. The loss of the swelling ability of the microsomes obtained from malignant tissue[14] is best explained by an alteration in the microsomal membranes. In the normal liver parenchymatous cell the endoplasmic reticulum exhibits a high spacial organization with numerous interconnected vesicles[15]. These structures provide "conditions of semi-isolation"[16] for certain complex enzyme systems and might thus exert a regulating influence upon them. Degradation of the lamellar barriers in the course of carcinogenesis establishes free access for metabolic products and enzymes to every part of the cytoplasm, and in this way seems to contribute to the uncontrolled turnover activity of the cancer cell.

I wish to express my indebtedness to Prof. Friedrich-Freksa for his generous guidance and constant support. The financial aid of the Studienstiftung des deutschen Volkes is gratefully acknowledged. This investigation is being continued and will be published in full elsewhere.

An Effect of Glucose on Bacteriophage Synthesis in *Salmonella typhimurium*

A MUTANT of *Salmonella typhimurium* has been obtained by Engelsberg (unpublished) which was characterized as 'diauxie-resistant' since, in contrast to the wild type, it could adapt itself to normally inducing substrates in the presence of glucose. The mutant was found by Engelsberg and Entner (unpublished) to contain three times as much glucose-6-phosphatase as the wild type. This enzyme difference suggests that the diauxie phenomenon can be explained by an extension of the hypothesis of Racker *et al.*[1] concerning the Crabtree effect, where it was suggested that glucose inhibits the utilization of endogenous materials by competing for the phosphate-nucleotide (adenylate) pool.

The present communication shows that an analogous glucose effect can be extended to bacteriophage synthesis. Glucose[2], bacteriophage infection[3], chloramphenicol[4], and amino-acid analogues[5] inhibit the induced synthesis of adaptive enzymes. Recently, it has been shown by Bertani[6] that during infection of some bacteria with certain temperate phages, the "selective inhibition of protein synthesis" by addition of chloramphenicol or amino-acid analogues causes a lysogenic response to be favoured over a lytic one.

With a multiplicity of infection much less than it can be demonstrated that when wild type *typhimurium* is infected with phage *P*22 (one of host-parasite pairs studied by Bertani), the presence of glucose also affects the course of infection in such a way as to favour the lysogenic response (Table 1). Under the same conditions but in the absence of glucose, a lytic response occurs. As might be predicted, the diauxie-resistant mutant is lysed either in the presence or absence of glucose.

Table 1. COURSE OF PHAGE *P*22 INFECTION IN *S. typhimurium* IN THE PRESENCE AND ABSENCE OF GLUCOSE (50–100 PHAGE ADDED PER PLATE)

	Lytic response (per cent)	Lysogenic response (per cent)
Wild type		
With glucose		100
No glucose	100	
Diauxie-resistant mutant		
With glucose	100	
No glucose	100	

In the experiments the method of Adams[7] was used to obtain infection responses. To 10^8 bacteria in 2 ml. of nutrient broth containing 0·7 per cent agar (45° C.) were added 50–100 bacteriophage, and the mixture was immediately shaken and poured on top of previously solidified nutrient agar plates. Glucose when present was added to a concentration of 1 per cent just prior to addition of phage. The lytic response is shown in Fig. 1*A* and lysogenic response in Fig. 1*B*. The papillæ in the centre of the halos in Fig. 1*B* can be shown to be lysogenic clones by use of the standard method of re-streaking isolated clones until free of phage and subsequent induction of phage synthesis by ultra-violet exposure. It should be pointed out that lysogenic bacteria can be also isolated from the centre of lytic plaques, but these are lysogenized through high multiplicity of infection many cycles after the initial lytic response[8].

It would appear plausible from these experiments that glucose and bacteriophage chromosome compete for the phosphate-nucleotide pool at common sites

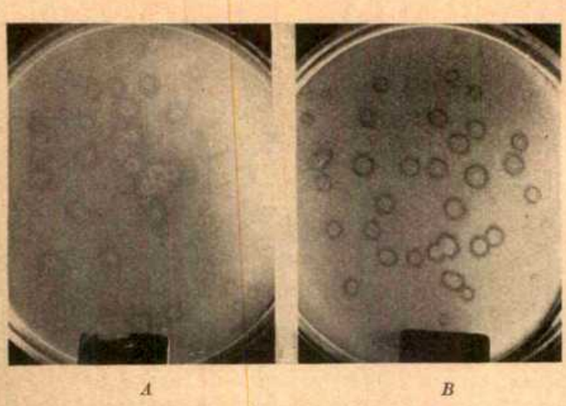

Fig. 1

involved in protein synthesis. A virulent phage, among other things, perhaps competes more successfully for this pool than a temperate phage. In wild type *S. typhimurium* cells, glucose, by having a greater affinity for the phosphate-nucleotide pool than phage chromosome, would inhibit phage protein synthesis as it does adaptive enzyme synthesis and the use of endogenous material. Lysogeny then results. The high glucose-6-phosphatase content of the diauxie-resistant mutant allows for the continual regeneration of the phosphate-nucleotide pool, and neither adaptive enzyme nor phage protein synthesis (with resultant lysis) is inhibited by glucose. These possibilities are being further investigated.

We acknowledge the help of a Lalor Foundation Award, which made the experiments reported here possible.

Identity of the Tetanus Toxin Receptor in Nervous Tissue

TETANUS toxin is thought to act by suppressing synaptic inhibition[1], and presumably it acts upon some substance at the inhibitory synapses in the grey matter of nervous tissue. As a possible approach to discovering the nature of this substance, the well-known Wassermann–Takaki phenomenon[2], that is, the fixation of tetanus toxin by the grey matter of nervous tissue, has been re-investigated.

Landsteiner and Botteri[3] showed that the water-insoluble sphingolipid fraction of brain had the greatest toxin-fixing capacity and believed that the cerebroside, phrenosine, was the specific toxin receptor substance; but they could not reconcile this with the fact that white matter is much richer in phrenosine than grey matter. It has now been shown that when sphingolipid suspensions are added to solutions of crude tetanus toxin, and of several other toxins, enzymes and other proteins, only the tetanus toxic protein is fixed. When the toxin is spun down with the sphingolipid, and the sphingolipid–toxin complex washed, the protein can be dissolved in alkali and estimated by the method of Lowry *et al.*[4]. It was found that 1·91 μgm. of protein was adsorbed for each $L+$ unit of toxin; this is in good agreement with the value of 2·02–2·15 μgm. protein per $L+$ unit for the pure crystalline toxin obtained by Pillemer *et al.*[5].

This specific adsorption of protein was used as the basis of an assay of the receptor. It was shown that when phrenosine was sufficiently purified it no longer fixed the toxin, and the receptor was evidently a contaminant. When crude phrenosine was partitioned between the two immiscible phases of a solvent system consisting of 15 parts chloroform, 15 parts benzene, 23 parts methyl alcohol and 7 parts water[6], little or no receptor activity could be recovered from either phase, but full activity was recovered when the two phases were recombined. Phrenosine, mixed cerebrosides or sphingomyelin could be substituted for the lower phase component. The upper phase component was found to a greater extent in grey matter than in white, was water-soluble, and on treatment with Bial's reagent yielded a pigment absorbing maximally at 570 mμ. In these properties it resembled the mucolipids[7] (ganglioside[8], strandin[9]), and it was found that both ganglioside and strandin could be substituted for the upper phase component.

The water-soluble mucolipids form complexes with the water-insoluble cerebrosides and sphingomyelins, which tend to be soluble in water when they contain excess mucolipid, but insoluble when calcium is incorporated in the complex. Unless the receptor were insoluble in water it could not be detected by the methods employed up to this stage, which depended on spinning down the receptor-toxin complex at 5,600*g*. However, it was found that when tetanus toxin (molecular weight[10] 67,000) and water-soluble mucolipid (molecular weight[7,9] 180,000–250,000) were mixed in solution and centrifuged at 114,400*g* for 2 hr., 84 per cent of the mucolipid and 82 per cent of the toxin in the upper half of the centrifuge tube migrated to the lower half, whereas only 29 per cent of the toxin migrated in the control tube containing toxin alone. Evidently the specific fixation is between the toxin and the mucolipid.

A detailed account of this work will be published in the *Journal of General Microbiology* (**20**, No. 2; 1959).

Loss of Sodium from the Skin of the Dehydrated Toad, *Bufo marinus*

THE movement of sodium across the skin of frogs and toads has been studied extensively[1]. *Bufo marinus* placed in distilled water loses sodium from the skin at an increased rate when injected with large doses of 'Pitressin'[2]. Increase in concentration of the body fluids as in dehydration potentiates posterior pituitary hormone release in mammals, and the same appears to be the case in amphibians[3]. Therefore it was of interest to see what effect such endogenous release of posterior pituitary hormone had on loss of sodium from the skin.

The loss was measured in normally hydrated toads during a 1-hr. period on three successive days. At the beginning of each measurement they were catheterized, thoroughly washed in distilled water and then placed in 150 ml. of this water for 15 min., rinsed again and finally replaced in 150 ml. of fresh distilled water. At the end of 1 hr. a sample of the fluid bathing the toads was taken and the sodium concentration determined with an EEL-flame photometer. The total loss of sodium was then calculated from the known volume of fluid bathing the toad. Apart from the experimental periods, the toads were kept in tap water. Care in handling ensured that urine was not voided while the measurements were being made. In a second series of experiments the same toads were left without water for 48 hr. at 21° C. and 55 per cent relative humidity during which time they lost 30·0 per cent (S.E. ± 1·25) of their body-weight—a degree of dehydration from which they readily recovered if replaced in water. At the end of this period loss of sodium from the skin was measured as before.

Table 1. LOSS OF SODIUM (MGM./HR.) FROM THE SKIN OF *B. marinus* UNDER NORMAL CONDITIONS AND DURING HYDRATION

Normal			Dehydrated
Day 1	Day 2	Day 3	
0·0516 ± 0·00336	0·0533 ± 0·00391	0·0582 ± 0·01232	0·3352 ± 0·06792

The results are the means ± S.E. in the same group of 15 toads (mean weight, 84·49 ± 2·800 gm.). Normal values all differed significantly from the dehydrated ($P < 0·001$).

The results are given in Table 1. It can be seen that the normal day-to-day rate of loss of sodium is remarkably constant, while in the previously dehydrated toads there is a marked increase in loss of sodium. The rate of loss is about four times as rapid as in *B. marinus* injected with large doses of 'Pitressin'[2]. The discrepancy may be due to a change in the concentration ratio across the skin and/or a change in the properties of the skin itself or to a greater effectiveness of endogenous hormone. In this latter respect it has shown that in *Bufo bufo* uptake of water is not as rapid after even supramaximal doses of posterior pituitary extracts as it is after the animals have been dehydrated[4].

Bathyscaphoid Squid

BUOYANCY equilibrium, or being of the same density as sea water, can confer a great economy of effort upon free-swimming animals and is approached or achieved in a variety of ways. While investigating buoyancy problems during a cruise of the Plymouth laboratory's research vessel *Sarsia* in the southern Bay of Biscay we found a particularly striking adaption in certain mid-water squid. Although some of the oceanic species resembled the coastal forms in being denser than sea water, the majority of the mid-water forms caught were in buoyancy equilibrium. Having neither cuttle-bone nor air sac they must have some other component less dense than sea-water (density = 1·026) to counterbalance the tendency of their proteins to sink.

These mid-water squid had enormous body cavities filled with fluid[1]. When the fluid, and it amounted to two-thirds of the squid's volume, was drained the squid sank; this showed that the buoyancy of the intact animals was given by the low densities of their coelomic fluids. From the volumes of coelomic fluid, the weights of the drained animals under sea water, and the density of that water, it was calculated that the fluid had a density about mid-way between that of distilled and sea water.

Samples of the coelomic fluid were collected from three species of mid-water squid (*Verrilliteuthis hyperborea* (Steenstrup), *Galiteuthis armata* Joubin, and *Helicocranchia pfefferi* Massy). These fluids, odourless but of bitter taste, were stored in a deep freeze and further studied on return to Plymouth.

The fluids from the three species were almost identical in composition and properties. Density-bottle measurements gave densities between 1·010 and 1·012, which accounted quantitatively for the buoyancy equilibria of the squid. Freezing point depressions were close to the value for sea water, showing that buoyancy was not achieved by simple exclusion of solutes. Of the common ions only ammonium can give a solution isotonic with sea water but of the density found. Tests indicated the presence of high concentrations of ammonium, and analyses by a method[2] insensitive to amines revealed about 480 mM ammonium. The sodium concentration was only about 80 mM, and chloride accounted for the necessary anion. (Sea water, which has chloride as its principal anion, has only a trace of ammonia but 490 mM sodium.)

The fluid's acidity, *p*H 5·2, was doubtless connected with the retention of ammonia in the coelom, for living tissues are permeable to molecular ammonia but relatively impermeable to the ammonium ion which predominates under acid conditions. The acidity accounted for the absence of ammoniacal smell during collection of the samples while the bitter taste of the fluid matched that of an ammonium chloride solution. We have prepared an artificial solution containing sodium and ammonium chlorides in the concentrations found in the coelomic fluid and shown that its density is close to that of the coelomic fluid.

These mid-water squid resemble the protozoan *Noctiluca*[3] in having a high concentration of ammonium ions which preserve tonicity and yet give buoyancy. In 'design' these squid are strikingly similar to the bathyscaphe, relatively recently devised by Prof. Piccard, in that their useful but dense parts are balanced by a large flotation chamber containing a fluid of lower specific gravity.

We would like to thank our colleagues at the Plymouth Laboratory for advice and help and Captain C. A. Hoodless and the crew of R.V. *Sarsia* for their enthusiastic co-operation.

Relationships between the Chloride and Iodide Uptake of Wheat Seedlings

THE theory that plants absorb ions by the action of carriers has become general during the past decades. It is an intermediate labile complex, formed by a combination of the carrier and the ion, which traverses the membrane impermeable to free ions. Upon arriving at the inner surface, the complex breaks down and releases the ion carried by it. Epstein *et al.*[1] suggest that different carriers are involved for different groups of ions. A common carrier mechanism is, for example, operative for chloride, bromide and iodide ions[2]. It was demonstrated a few years ago that two separate systems of carriers act in the uptake of differently dissociated phosphate ions[3], while, recently, likewise two separate carriers have been postulated for the absorption of monovalent cations[4]. It has thus become necessary to collect additional data concerning the uptake of monovalent anions.

The results of experiments performed by Sutcliffe[5] with disks of red beetroot point to the possibility that mutual interference between the uptake of different alkali ions is more intricate than used to be supposed. If an ion *A* is a competitive inhibitor of the uptake of another ion *B*, the latter may either inhibit or stimulate the uptake of *A*, according to whether the carrier exhibits a preference for its absorption. Sutcliffe claims the existence of such interaction between sodium and potassium. We are not aware of this kind of correlation between other pairs of ions, probably for the reason that mutual interference between the uptake of different ions has been investigated mostly in one direction only.

Seedlings of winter wheat, variety *F.* 481, were used in our experiments. We sterilized the seeds with hydrogen peroxide and then germinated them in Petri dishes for two days at a temperature of 26° C. The seedlings were transferred to perforated disks and the latter placed upon the surface of a tenfold-diluted Hoagland solution. The plants were then grown for two more days in the nutrient solution at 21° C. After this, the seedlings, with the perforated disks, were transferred to Lundegårdh vessels for the purposes of 24-hr. experiments, which, like the growing of the seedlings, were performed in the dark, in a damp atmosphere.

Combining five chloride- and five iodide-levels (0, 0·5, 5, 25 and 50 m.equiv.) we obtained twenty-five variants. At the termination of the experiment, the roots were twice rinsed with distilled water, after which the roots and the shoots were dried separately. (Seeds were not analysed.) The samples were burnt in oxygen[6], and this was followed by electrometric titration. After having acidified the solution, the released iodine was dissolved in chloroform and measured photometrically. Uptake is given in μ.equiv. in respect of the test plants used in each variant. Figures represent the mean value of results from two replications.

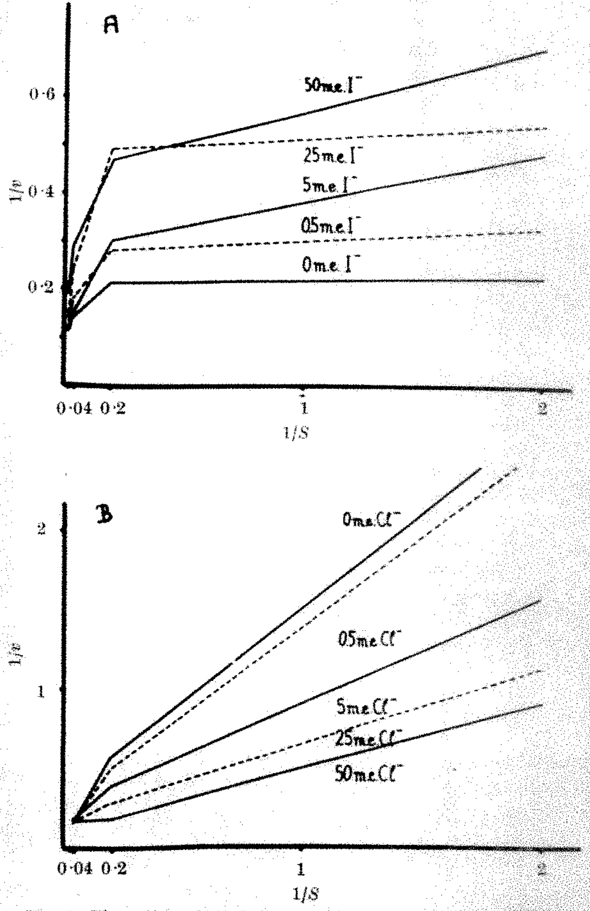

Fig. 1. The action of iodide levels on the accumulation of chloride (*A*), and the action of chloride levels on the accumulation of iodide (*B*) in the roots

As usual, the reciprocal of the rate, at which the roots accumulate chloride and iodide, $1/v$, is plotted against the reciprocal of concentration $1/S$ (Fig. 1, *A* and *B*). Lines so obtained are characteristically curved for both ions: this points, according to the kinetic analysis, to the participation of two carrier

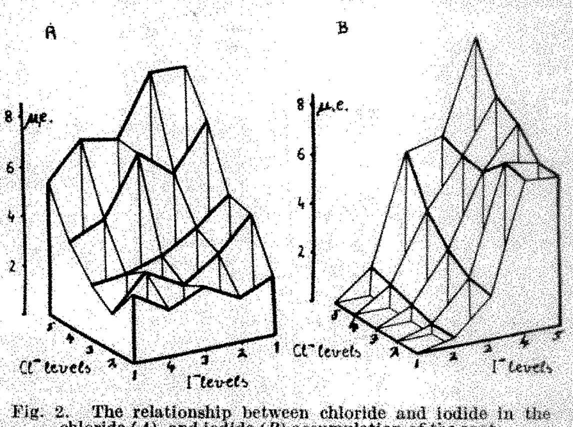

Fig. 2. The relationship between chloride and iodide in the chloride (*A*), and iodide (*B*) accumulation of the roots

systems. On plotting v against v/S we obtain likewise curves which are perfectly similar to those described by Fried and Noggle[4]. (It should be noted that we did not deduct the original chloride content of the roots as we had the impression that, at higher iodide concentrations, it dropped below the initial value.) We regard the deviation of our results from those of earlier authors as a result of experiments over a wider concentration-range.

That chloride and iodide ions exercise different effects on the absorption by the roots is well shown in Fig. 1, and this phenomenon is still more conspicuous from the stereo-diagram (Fig. 2). In order to make it clearer, the respective chloride and iodide levels have been plotted on the two abscissæ equidistantly and not at the points corresponding to the actual concentrations. Increase in iodide concentration inhibits chloride uptake while, surprisingly, increased chloride concentration stimulates iodide accumulation.

Represented by a double reciprocal plot, the accumulation of chloride and iodide in the shoots follows the same course as described in connexion with the roots. The stereodiagram clearly reveals the strong inhibitory effect of iodide on chloride accumulation. In contrast to what has been said concerning roots, the stimulatory influence of chloride on iodide uptake cannot be observed except at low iodide concentrations.

Further details of our results, and data regarding the relationships between chloride–bromide and bromide–iodide, will be published in the *Acta Botanica Hungarica*.

Fixation of Nitrogen-15 by Excised Nodules of *Coriaria arborea* Lindsay

Bond[1] has recently directed attention to the occurrence of root nodules on species of *Coriaria* growing in New Zealand. We have found nodules on young plants of *C. arborea* but not on *C. sarmentosa*. The other five species of *Coriaria* recognized[2] as occurring in New Zealand have not yet been examined for nodules. *C. japonica*, endemic in Japan, has long been known to be nodulated, and evidence has been produced indicating its capacity for nitrogen fixation[3].

In the experiments reported here, whole plants of *Coriaria arborea* were dug in the field and brought into the laboratory with the root systems tied into plastic bags to guard against excessive loss of water. Nodules and nodule clusters were then excised, brushed free of adhering soil, washed and placed in contact with a nitrogen-free inorganic nutrient solution in a glass container. Each sample consisted of several nodules and nodule clusters with a total fresh weight of 3·4 gm.

The container was evacuated to 0·5 atmosphere and then the pressure was restored to atmospheric by the introduction of nitrogen containing approximately 60 atom per cent nitrogen-15. The gas mixture surrounding the nodules now contained approximately 10 per cent oxygen and 90 per cent nitrogen with 30 atom per cent excess nitrogen-15. The time-intervals between digging the plants and exposing the nodules to nitrogen-15 did not exceed 50 min. The nodules were left in the darkened container for 24 hr. at laboratory temperature of 27 ± 2° C. and then extracted with 3 N hydrochloric acid[4]. The extract of a single sample contained approximately 3·0 mgm. nitrogen. Distillates from Kjeldahl digestions of the extracts were submitted for nitrogen-15 assay to the Division of Nuclear Sciences of the Department of Scientific and Industrial Research.

Acid extracts of three samples of nodules were found to contain 0·89, 0·71 and 0·51 atom per cent excess nitrogen-15, giving clear evidence of the fixation of nitrogen-15.

We wish to thank Mr. J. A. Rafter, director of the Division of Nuclear Sciences, Department of Scientific and Industrial Research, and Dr. A. D. Campbell of the Chemistry Department, University of Otago, for their advice and collaboration in this work which has been aided by a grant from the University of New Zealand Research Fund.

Growth-promoting Effect of Ethanol on Oat Seedlings

The effects of carbon dioxide on the growth of etiolated oat seedlings[1]—promotion of the mesocotyl and depression of the coleoptile—have been under investigation for some time[2,3] and the observed behaviour has been attributed to a prolongation of the activity of the nodal meristem[2]. Attempts have recently been made to correlate these growth phenomena with auxin metabolism by supplying indoleacetic acid (10 p.p.m.) to intact oat seedlings via their roots. In these experiments promotion of the mesocotyl was observed when ethanol was used as the solvent for indoleacetic acid but not when the potassium or ammonium salts were used dissolved in water. The effects on growth of 0·2 and 0·3 per cent ethanol were investigated, and they occasioned growth responses which exactly parallelled those induced by carbon dioxide.

The measurements of fifteen replicates per treatment (mm.) recorded in Table 1 were derived from an experiment in which plants were pretreated in darkness with ± carbon dioxide (5 per cent) ± ethanol (0·3 per cent) for 3 days from the time of planting, after which one set was exposed to dim red light (1 foot-candle) for 5 min. while the other set remained in darkness, and these were measured when 7 days old. The duplicate initial measurements (3 days old) thus estimate the lengths of the plant organs at the time of exposure to light, and, since no further treatment with ethanol and carbon dioxide was given, the subsequent growth responses were after-effects.

Table 1. LENGTHS, IN MM., ATTAINED IN THREE DAYS BY OAT SEEDLINGS BEFORE ILLUMINATION. EACH ENTRY IS THE MEAN OF FIFTEEN REPLICATES

Carbon dioxide	+	−	+	−	+	−	+	−
Ethanol	+	+	−	−	+	+	−	−
Mesocotyls	10·3	16·1	21·1	32·7	11·2	15·9	22·1	31·8
Coleoptiles	4·7	7·3	6·8	12·1	4·5	6·8	7·1	10·3
	Lengths of plants (mm.) when seven days old							
	Illuminated				Not illuminated			
Mesocotyls	76·2	57·4	56·7	46·0	123·7	91·6	96·8	58·0
Coleoptiles	48·5	58·6	63·1	66·0	43·8	60·8	61·6	72·8

The growth of both mesocotyls and coleoptiles was depressed by each factor during pretreatment, and the administration of both simultaneously was more depressive than either singly.

Between 3 and 7 days in darkness both treatments induced promotion of the mesocotyl to approximately the same extent (increment 33·6 and 38·8 mm.) while the combined effect (increment 65·7 mm.) was almost equal to the sum of the individual effects. After illumination the untreated mesocotyls (−carbon dioxide, −ethanol) increased in length by 13·3 mm., but the depressive effect of light was almost eliminated by pretreatment with either carbon dioxide or ethanol (compare 56·7 and 57·4 with 58·0 mm.), while the combined effect was promotive (compare 76·2 with 58·0 mm.). These treated plants were nevertheless very sensitive to light, which depressed mesocotyl growth from 123·7 mm. to 76·2 mm., a proportionately greater decrease than that shown by the controls 58·0 to 46·0 mm.); similarly with each factor separately.

In connexion with the suggestion that carbon dioxide prolongs the meristematic phase, it may now be said that ethanol does likewise, and it is therefore of great interest that it has recently been shown that ethanol stimulates cell division in algæ[4,5].

Further data and a discussion of the significance of these findings will be published shortly. Meanwhile the matter is under investigation.

Host Specificity in *Xanthomonas*

Burkholder and Starr[1] stated that "unequivocal identification by laboratory procedures of all *Xanthomonas* species is as yet an impossibility", and there has been no change in this position in recent years[2,3]. The diagnosis of *Xanthomonas* species therefore depends on the host specificity of the organisms. Wernham[4] inoculated cultures of fourteen pathogenic *Xanthomonas* into twelve different hosts and found them to be "remarkably specific in their host reactions". He also stated that "there is no possibility of error in using the host as a species determiner". However, since the host ranges of most of the organisms have never been completely determined the classification of the genus is not securely established.

* ITCC, Indian Type Culture Collection, New Delhi, India; NCPPB, National Collection of Plant Pathogenic Bacteria, Harpenden, Britain; ATCC, American Type Culture Collection, United States.

Recently, some cross-inoculation tests were carried out as follows: bean plants (*Phaseolus vulgaris* L.) variety Canadian Wonder, were grown from seed in sterilized soil in sterilized 4-in. pots. When the first trifoliate leaves were half developed the plants were placed for 24 hr. in a cabinet into which a fine mist of sterile water was automatically sprayed for 45 sec. every 30 min. Leaflets were then punctured in the midrib with a sterile needle. A small quantity of each of the *Xanthomonas* cultures listed in Table 1 in yeast-extract nutrient broth (yeast extract, 'Difco', 5 gm.; peptone, 5 gm.; 'Lab-lemco', 5 gm.; water, 1 l., *p*H 6·8) which had been incubated at 27° C. for 24 hr. was then placed on the leaflets by pipette. Inoculum was also placed on the unfolding second trifoliate leaves, which were not punctured. Each plant was immediately covered with a transparent plastic bag which was tied tightly around the pot in order to provide a humid atmosphere about the plant. After 3–5 days the plants were examined and isolations were made from lesions. If no lesions were apparent isolations were made from the points of needle puncture. Xanthomonads were re-isolated without difficulty in all instances. Three isolates, each from a different lesion or puncture, were incubated for 24 hr. in yeast-extract nutrient broth. The three cultures were then mixed and inoculated into fresh bean plants as before. The object of combining the three isolates was to reduce the chances of using non-pathogenic mutants. The process of inoculation, isolation and re-inoculation was carried out four times. On the last occasion lesions were allowed to develop for seven days before the result was recorded. A progressive disease was produced by the cultures listed in Table 1. Dark green to black, angular lesions 2–4 mm. in diameter appeared at the sites of puncture, and the veins showed browning and collapse for 3–5 mm. Some lesions as they aged became light brown. Yellow chlorotic areas developed around many lesions. On parts which had not been pricked, dark green water-soaked angular spots developed, particularly on the younger leaves (Fig. 1). When lesions coalesced the effects were frequently severe and caused defoliation. Some lesions extruded a slimy mass of bacteria which were found to be xanthomonads.

The lesions which developed without the tissues having been damaged were regarded as good reproductions of natural infection and were considered as

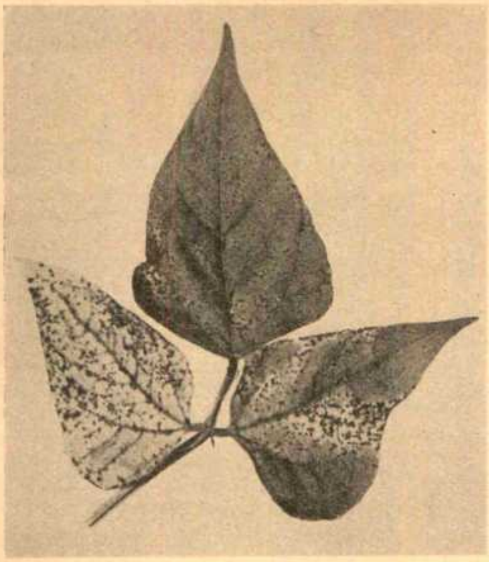

Fig. 1. The typical effects produced on bean leaves by the various species of *Xanthomonas*

proof that the bacteria had become adapted to their new host. This type of infection could not invariably be distinguished from that caused by *X. phaseoli*, though this organism frequently caused a more extensive pale green necrosis and wilting. It seems possible that the organisms originally isolated from other hosts would, with further adaptation to the bean, produce symptoms identical with those due to *X. phaseoli*. Single-colony isolates were in each case shown to be indistinguishable in cultural and physiological properties from their parent culture. The ability of *X. phaseoli* var. *fuscans*, *X. punicae* and *X. ricinicola* to produce a brown stain in media was a convenient label for these organisms, and provided evidence that unintentional cross-infections did not occur.

There seems to be no reason to suppose that the inoculations were carried out under unnatural conditions. Actively growing bacteria were merely applied in sufficient numbers to susceptible parts of bean plants under the conditions of humidity and temperature which commonly promote infection in temperate and sub-tropical climates. The findings suggest the possibility that a similar result might be obtained with other hosts and that the host specificity of the xanthomonads may not be a stable character. The fact that cultures originally isolated from twenty different hosts can infect bean plants is, at the least, evidence of a close relationship among these organisms.

I am grateful to the New Zealand Fruitgrowers Federation, Ltd., and to the Department of Scientific and Industrial Research, New Zealand, for financial assistance which made this work possible.

Preparation of Virus Antisera from Strawberry

STRAWBERRY contains tanning agents in such quantity that water extracts of strawberry leaves contain no appreciable amounts of protein and will, moreover, precipitate serum proteins, thus being unsuitable for serological work with viruses that infect the plant[1]. This is also true of other rosaceous plants, and thus most workers have tried to find other hosts for viruses affecting members of the Rosaceae before attempting the preparation of specific antisera.

It now seems that this step is not necessary in preparing antisera to some viruses from rosaceous plants, since by the use of recent techniques for the removal of tanning agents from leaves during maceration[2], satisfactory antisera have been prepared to two viruses from strawberry leaves, namely, raspberry ringspot virus from the variety Huxley, and raspberry yellow dwarf virus from the variety Cambridge Favourite. Both these are soil-borne viruses which are widespread and of local importance in strawberry in Scotland, and they can be transmitted mechanically from strawberry to a number of herbaceous host plants[3].

In each case, leaf extracts were prepared by the following method, found to give a high yield of virus in preliminary investigations in which extracts prepared in various ways from Huxley strawberry infected with raspberry ringspot virus were assayed on the leaves of *Chenopodium amaranticolor* (Coste and Reyn.) plants.

Mature leaves harvested from infected plants in the field were shredded and then ground in a mortar with an equal weight of 5 per cent nicotine base and sufficient coarse carborundum powder to ensure thorough maceration. The liquid expressed by squeezing the macerate through muslin was then clarified by slow-speed centrifugation and dialysed against running tap-water overnight to remove excess nicotine. After further dialysis against 0·85 per cent saline, the preparations were stored frozen. Antisera were prepared by the intravenous injection to rabbits of 2 ml. aliquots of these preparations at twice-weekly intervals over a period of three weeks. Both antisera were of moderately high titre—about 1/256—measured by precipitin tests against clarified sap from infected leaves of *Petunia hybrida* Vilm. This titre compares well with those obtained using infected *P. hybrida* or *Nicotiana tabacum* L. as the source of virus[4]. It is of interest that the viruses in preparations made in this way did not give a visible precipitate when incubated with their homologous antisera, but did so only if concentrated after precipitation with acetone.

It is thought that this method, refined by the use of ultracentrifugation or freeze-drying, may be of value in preparing antisera to other viruses directly from rosaceous hosts. A fuller account of the development of the method is to be published elsewhere.

Sol-Gel Transitions in the Living Cells of Conifers and their Relation to Resistance to Cold

THE cause of cold hardiness changes in over-wintering phanerophytes has long been sought in the characteristics of the cytoplasm. Yet there are sharp disagreements on whether the cytoplasm becomes more viscous or less viscous in winter. At the same time the characteristics of the vacuole have not been so carefully studied by cytologists. Both Iljin and Rouschal[1], however, believed that the extraordinary drought resistance of certain ferns was related to the ability of the vacuoles to gelate.

Such a gelation could occur in the leaves and bark of over-wintering plants like pines and thus stabilize the cytoplasm against distortion during the dehydration accompanying ice formation. Gelation of the cell contents of trees has been mentioned in the literature; but observations are not supported by clear evidence. Some have felt that the gelation is 'protoplasmic', at least in cambial cells of trees[2]; yet others have left it open to question as to the exact part of the cell gelating[3,4]. In the meantime, others have concluded that the cytoplasm becomes more fluid in winter than in summer[5], so that gelation or even increased viscosity (an idea supported by numerous workers) would seem unlikely. Observations of protoplasmic streaming in pine cambial cells[6] would seem to throw light on the matter; but protoplasmic streaming is probably not a good measure of viscosity, and streaming is commonly lacking in many of the mature living conifer cells in any season.

In our work it became clear that in the endodermis and transfusion parenchyma cells of the leaves of *Pinus ponderosa*, *P. strobus* and *P. monticola*, the vacuoles pass from a sol to a gel condition in the late autumn, that is, from a liquid of about 3 on the viscosity scale of Seifriz[7] to one of about 8. This was indicated by a marked slowing down and finally a cessation of Brownian movement of vacuolar particles. It is believed that this phenomenon may contribute to, although not explain, the autumn hardiness increases.

Another curious thing observed in the course of seasonal microscopic studies of *P. strobus* bark cells was that the starch grains sink down in the ray cells due to gravity alone in January and remain thus into March. At the same time nuclei in the adjacent vertical phloem parenchyma were often found to be acropetal. In summer it was necessary to centrifuge bark cells at 1,500 r.p.m. in order to throw down the starch grains. This suggests a decreased cytoplasmic viscosity in winter, to use the terminology of Heilbrunn[8], and might even be considered a gel-to-sol transition.

Genetical Interference in *Drosophila* spp.

IN chromosomes II and III of *D. melanogaster* Owen[1] found good agreement with the interference function $4u\exp(-2u)$ which is distributed as $\frac{1}{4}\chi^2_4$. In the X-chromosome the position was more doubtful, possibly due to misclassification, which tends to inflate the rare double recombinant classes in multi-point linkage tests, hence altering the estimates of the intensity of interference.

It was therefore thought profitable to examine back-cross linkage data involving three or more genes in some of the other species of *Drosophila*. The method of analysis has been sketched by Parsons[2,3]. This involves plotting the Kosambi coefficient[4], K, against the mean of the map distances for each three point test. On the $\frac{1}{4}\chi^2_4$ metric, $K = 1$ at the metrical mid-arm of long chromosome arms, which corresponds to a point one-third of the map distance from the centromere. Closer to the centromere $K > 1$, and farther from it $K < 1$. Thus graphs of K against the mean of the map distance may be compared with an expected graph, and if the centromere can be located accurately the observed metrical mid-arm may be compared with the expected, as has been done for maize[2,3].

Data for the six species *D. simulans*, *D. virilis*, *D. sub-obscura*, *D. prosaltans*, *D. pseudo-obscura* races *A* and *B* and *D. willistoni* were examined. In many cases the K values were very variable. Some of the variability was removed by eliminating genes prone to misclassification, but some remained, and may possibly be due to gonial crossing-over[5]. In the data for *D. prosaltans*[6], for example, cross-over values and hence K values varied enormously. In the X-chromosome the K values increased towards the centromere, showing that interference is less intense near the centromere. In chromosomes II and III, the situation was not obvious, possibly due to a lack of data.

On the whole, however, with the exception of the X-chromosome of *D. virilis*, the K values were less scattered, and a definite graph of K increasing towards the centromere could be drawn for the X-chromosomes of *D. simulans*, *D. pseudo-obscura* race *B* and *D. willistoni* (Brazilian and Cuban strains), chromosome II of *D. simulans* and *D. pseudo-obscura* race *A*, and chromosome III of *D. pseudo-obscura* race *A*. In the X-chromosomes of *D. sub-obscura* and *D. pseudo-obscura* race *A*, and chromosome III of *D. simulans* there was no apparent trend, but the points did not disagree with expectation. For the remainder of the chromosomes the data were inadequate.

Thus the well-established phenomenon of interference becoming more intense with distance from the centromere is not contradicted. However, on the whole, the data are very much more variable than in maize[2,3], and testing them against a specific metric does not appear to be possible. It can be said that it is unlikely that interference is much more severe than that predicted by the $\frac{1}{4}\chi^2_4$ metric, for on the $\frac{1}{6}\chi^2_6$ metric developed by Payne[7], K is expected to be $<0{\cdot}3$ at 20 to 30 centimorgans from the centromere. Most of the observed values in this region were much closer to unity, which represents the degree of interference predicted by the $\frac{1}{4}\chi^2_4$ metric.

However, it cannot be expected that all the data will fit one metric, since a metric, like recombination, varies according to genetic and environmental conditions. To specify the situation fully, it is probable that a family of interference functions of similar form will be needed. Behind every interference function there must be some basic assumption.

which, on observations and theory to date, must be[1,4]: (1) no interference across the centromere; (2) independent distribution of intercept-lengths when measured on an interference metric; (3) no repressive effect of the terminus on chiasma formation. Presumably, therefore, each metric will be of similar form. A small adjustment will allow for changes of the environment or genetic background, and in some organisms, such as the house mouse[8], a different metric will be needed for each sex.

Resistance to Pyrethrins and to Pyrethrins - Piperonyl Butoxide in a Wild Strain of *Musca domestica* L. in Sweden

Although synergized pyrethrins have been used for fly control for many years, there is no published record of *Musca domestica* L. becoming resistant to this insecticide in the field.

During 1947–56, the fly population of a farm (Wasa) near Stockholm had developed high resistance to many of the chlorinated hydrocarbon insecticides and some resistance to parathion. Commercial insecticides containing pyrethrins and the synergist piperonyl butoxide were used in the latter part of 1956 and early 1957, but by October of that year it was reported that they no longer killed the flies.

Larvæ and pupæ of *Musca domestica* L. were collected at this farm and bred under standard conditions at the Statens Skadedyrlaboratorium, Springforbi, Denmark, and the Cooper Technical Bureau, Berkhamsted, England.

At Springforbi the resistance of the first and later generations was measured by topical application to the dorsal thorax of female flies of a mixture of pyrethrins plus piperonyl butoxide (1 : 10) dissolved in acetone. The mortality was observed after 24 hr. and the median lethal dose (*LD*50) per 20 mgm. of fly estimated from plotted regression lines. Comparative tests were carried out with laboratory strains representing various resistance patterns, which, as far as we know, have not been exposed to selective treatment with pyrethrins.

Table 2. Resistance to Pyrethrins and to Pyrethrins plus Piperonyl Butoxide of a Wild Strain of *Musca domestica* L. collected from a Farm in Sweden

Spray tests with oil solutions. (Means of six replicate tests)

Strain of *Musca domestica* L.	Percentage concentration (w/v) of insecticide Pyrethrins	Piperonyl butoxide	Percentage mortality in 24 hr.	*LD*50 (percentage concentration)	Resistance	*KD*50c (min.)
Laboratory	0·10 0·25 0·40 0·50	— — — —	14 45 54 61	0·32	1	2·60 1·75 1·30 1·15
Swedish (Wasa)	3·25 4·00 5·00 7·00 10·00	— — — — —	35 51 58 82 87	4·00	12·5	>10 >10 >10 >10 >10
Laboratory	0·03 0·04 0·05 0·075	0·24 0·32 0·40 0·60	42 48 65 91	0·041/0·328	1	4·20 3·30 3·10 2·30
Swedish (Wasa)	0·30 0·50 0·625 0·75	2·40 4·00 5·00 6·00	21 59 83 93	0·44/3·5	10·7	>10 >10 >10 >10

The results (Table 1) showed that the *LD*50 of the Wasa flies (3·3 µgm.) was 11–14 times that of the susceptible strains Enø and 7. After seven generations in the laboratory without exposure to insecticides, the resistance of the Wasa strain decreased significantly but was still remarkably high (2·1 µgm.).

Moreover, the Wasa strain showed high resistance to chlorinated hydrocarbons, and the *LD*50 obtained with the organo-phosphorus compounds, 'Diazinon' (1·2 µgm.; 30 times normal) and parathion (0·13 µgm.; six times normal) was comparable to the highest measured in Danish field-populations[1].

The laboratory strains which were resistant to chlorinated hydrocarbons or organo-phosphorus compounds are also more tolerant to synergized pyrethrins than normal (2–4 times). This indicates that the resistance to synergized pyrethrins is partly due to non-specific factors ('vigour tolerance') and partly to specific defence mechanisms against synergized pyrethrins.

At the Cooper Technical Bureau the resistance of the F_3 generation to pyrethrins, and to pyrethrins plus piperonyl butoxide in a ratio of 1 : 8, was compared with that of the normal laboratory stock. Flies were sprayed with solutions of these insecticides in odourless kerosene. A modification of the direct-spray technique evolved by Kearns and March[2] was used.

Table 1. Tolerance to Pyrethrins and Piperonyl Butoxide of a Swedish Strain (Wasa) of *Musca domestica* L. compared with Danish Strains

Topical application of acetone solutions

Strains	Year of collection	Resistance to: DDT	Lindane	Chlordane	Organo-phosphorus compounds	Tolerance to pyrethrins/piperonyl butoxide, 1 : 10 — *LD*50 µgm. per female fly (20 mgm.) with 95 per cent confidence limits	Slope
Swedish							
Wasa F_1	1957	+++	++	+++	++	3·3 (2·9–3·7)	6·3
Wasa F_8	1957					2·1 (1·8–2·4)	6·3

No. 150*a*	1955	+			+	0·52 (0·43–0·63)	4·3
No. 203*a*	1957	+++	++	++	++	0·98 (0·76–1·29)	2·4

Symbols for resistance: +++, high; ++, moderate; +, slight; –, none.

The concentration of insecticide required to give 50 per cent mortality (*LD*50) was calculated for each insecticide with each strain of flies from log probit regression lines. Knock-down was recorded in addition to the percentage mortality and the *KD*50c (time taken to knock down 50 per cent of flies) obtained with each solution was calculated.

The results (Table 2) showed that the Wasa strain was 12·5 times more resistant to pyrethrins, and 10·7 times more resistant to pyrethrins plus piperonyl butoxide, than the normal laboratory strain. Resistance to the knock-down effect of these insecticides was also shown.

It may be of interest to other workers to note that preliminary tests carried out at the Cooper Technical Bureau have indicated a resistance to 'Allethrin' and to 'Allethrin' with piperonyl butoxide. Using a measured drop technique, resistance to 'Allethrin' was about 150 times, and to 'Allethrin' with piperonyl butoxide about 45 times, that of the normal laboratory strain.

The conditions for development of this reported resistance seem to have been especially favourable in Sweden during the past few years. As the chlorinated hydrocarbons and organo-phosphorus compounds failed to control the flies, dusts with a low content of synergized pyrethrins (at Wasa 0·075 per cent pyrethrins plus 0·6 per cent piperonyl butoxide) were used widely throughout the fly seasons, and flies were exposed to a wide range of dosages as the pyrethrins deteriorated. In addition, aerosols containing concentrations of synergized pyrethrins below that normally required for adequate fly control were used. Increasing difficulty in killing flies with pyrethrum insecticides, both dusts and aerosols, was reported from several places in Sweden in 1957, but the resistance was not measured by laboratory tests.

Changes in the Tiller Population of Grass Swards

ONE of the characteristic attributes of perennial herbage grasses is their ability to produce tillers in large numbers. Since each tiller, in passing through its life-cycle, lives for a variable but limited amount of time, the growth of the plant will reflect the sum of the individual life-histories of its tillers. There is continuous change throughout the year as new tillers appear and others decay, so that counts of tillers at any one time represent no more than a census of an ever-changing population.

Discernible seasonal trends in the number of tillers present in the sward have been shown in several species. The indications are that density of tillers increases after the summer, possibly continuing into the winter, but that after the onset of active growth in the spring a marked decline occurs[1,2] which may be prolonged and severe if growth is allowed to proceed uninterruptedly[3]. A cut at the hay stage when ears have emerged will remove large numbers of tillers which may not be replaced immediately, thus leading to a further decrease in the tiller population.

Table 1. NUMBER OF LIVING TILLERS PRESENT PER 1 SQ. F

1958	Hay and aftermath		Frequent cutting	
	Meadow fescue	Timothy	Meadow fescue	Timothy
March	606	526	823	[illegible]
April	578	542	822	[illegible]
May	522	361	718	675
June	504	264	484	504
July	524	319	516	[illegible]
August	439	314	531	614

Recent experiments, in which the performance of individual tillers of plants growing in large containers but otherwise under field conditions has been followed, suggest that these fluctuations in number are accompanied by considerable changes in the composition of the population in respect of age, as tillers come and go. These changes do not appear to be confined to swards which are cut for hay after flowering has occurred, as would have been expected, but also occur in frequently defoliated swards in which inflorescences are not allowed to appear.

Table 1 shows the results of a census of the number of tillers starting in March 1958 and repeated at intervals of 4 weeks. The swards under investigation were either *S*.215 meadow fescue or *S*.48 timothy sown without clover in 1956 and subjected to one of two managements: cutting for hay and aftermath, or frequent cutting (every 4 weeks beginning early in April). Both grasses maintained a greater population of tillers in response to frequent cutting than under the hay and aftermath system. Within each treatment, tiller numbers tended to be high early in the year but they declined after the middle of April, whether the swards had been cut by that time or left to grow until ears had emerged (late May in meadow fescue, late June in timothy).

These seasonal variations in number were accompanied by marked changes in the composition of the tiller population, as shown by the number of new and dead tillers at each date of observation (Table 2). For the purpose of this study no distinction was drawn between tillers which had died from natural and unspecified causes, and those that had been killed by having their apical meristem removed through cutting.

In both meadow fescue and timothy, cutting for hay after ears had emerged led to heavy casualties among tillers, but replacement appeared to be rapid and roughly proportional to the losses sustained. As

Table 2. NUMBER OF NEW AND DEAD TILLERS PER 1 SQ. FT.

1958	Meadow fescue		Timothy	
	New	Dead	New	Dead
	Hay and aftermath			
March	34	26	42	22
April	29	57	27	11
May	35	91	2	183
June	226	269	138	229
July	70	50	146	96
August	39	124	77	82
	Frequent cutting			
March	74	41	23	22
April	21	42	37	37
May	52	156	16	116
June	98	332	234	404
July	40	9	236	167
August	57	42	122	58

a result, a large part of the tiller population in August was of fairly recent origin. Similar changes also occurred under a system of repeated defoliations, although ears were never allowed to appear. Thus in timothy, about 690 tillers per sq. ft. died or were decapitated between May and July, while some 490 new tillers appeared. Heavy losses were also recorded in meadow fescue; replacement was less rapid, but the results obtained in the previous year suggested that in this grass tillering continues actively into the winter. Although no marked fluctuations in tiller numbers could be detected, there had nevertheless been considerable change in the composition of the tiller population, with most of the older tillers disappearing and new ones taking their place.

A large part of these internal changes was no doubt attributable to the fact that many tillers had moved from the vegetative to the reproductive condition at a time determined by the day-length requirements of the plant. After this transition had gone some way, internode elongation will have occurred, so that in course of time differentiated shoot apices were lifted sufficiently high above the ground to become vulnerable to cutting. This would account for the high casualties sustained by both grasses around the time when they usually flower if allowed to produce ears.

In consequence of this striking loss and replacement of tillers, the composition of swards in August was very different from that earlier in the year. It may be suggested that these differences play a part in the seasonal pattern of dry-matter production in the grasses. Tillers which appear in the autumn or winter are usually well established by the time environmental conditions favourable for growth arise in the spring. There then follows a period of intense accumulation of dry-matter, characterized by exceptionally high growth-rates[3] and continuing to around the time when flowering occurs. Whether inflorescences are allowed to emerge or not, a cut taken after internode elongation has gone some way will result in the removal of a large part of the older tillers and their replacement by new shoots. Since very young tillers appear to go through a period of establishment[4], the plant may not be able to continue production of dry-matter at the same rate as in the pre-flowering period, before the tiller complement was changed. This may be more noticeable under difficult climatic conditions and in strains which naturally flower late and thus produce tillers when some environmental factors are no longer optimal. It is thus possible that the decline in the productivity of grasses commonly experienced in the summer is connected with the change in the tiller population, even though no indication of this can be obtained from tiller counts. The suggestion of breeding non-flowering strains to overcome this problem has already been put forward[5], although there may possibly be other means of ensuring that a greater proportion of the tillers present early in spring survive through the summer and contribute to the total dry-matter production of the plant.

Importance of Taxonomy in Biological Investigations

Often in biological investigations no attempt is made to define with precision the species upon which the investigation was carried out. Terms without specific connotation, such as 'frog' or 'monkey', are used. This lack of precision may mean that data are lacking which may afterwards prove to be of significance in relation to the purpose of the paper.

Another reason why precision in identification of species is desirable is that there is probably much to be gained from a greater integration of knowledge obtained by investigation of living forms with our knowledge of taxonomy, gleaned in large measure from the fossil record of extinct forms. This will only be possible if all types of biological investigators pay attention to the taxonomical classification of the subjects of their study. Such a correlation of knowledge should reflect to the benefit not only of taxonomy but also of biological science in general. So far as comparative anatomy is concerned, a closer consideration of taxonomy and modern concepts of the relation of groups in the evolutionary process should prevent the hasty drawing of false homologies between structures which are only superficially similar.

The following example indicates the mutual benefit that may derive to descriptive anatomy and taxonomy by attempting correlation between them. Among selachian fishes (that is, members of the sub-class Selachii of the class Elasmobranchii[1]) fusion of the two lateral telencephalic lobes of the forebrain occurs, except in *Scymnorhinus*, in which the lateral telencephalic lobes remain unfused. The primary site of attachment of the nervus terminalis is on each side lateral to the lamina terminalis, but this is only clearly seen in the mature brain in *Scymnorhinus*. In other forms the proximal part of the nerve is incorporated in the brain by the fusing telencephalic lobes, the nerve being carried either dorsally or ventrally in this process, so that its definitive site of superficial attachment is either dorsal or ventral[2]. The nervus terminalis in selachians[3] is thus attached in some forms dorsally to the forebrain and in others ventrally. If the various forms are viewed merely as a number of selachians, this detail of descriptive anatomy, concerning as it does a minute nerve of uncertain function, can scarcely seem to be of much interest, especially when it is remembered that the definitive site of attachment of this minute nerve is secondary, being dictated probably by largely mechanical factors during fusion of the telencephalic lobes. However, if the forms in which the site of attachment of the nervus terminalis has been recorded are reviewed from a taxonomical point of view, it is found that the attachment is dorsal in the skates and rays (sub-order Hypotremata, order Euselachii); and, among the sharks of the order Euselachii, which are classified as the sub-order Pleurotremata, it is dorsal in the superfamily Squaloidea (except in *Scymnorhinus*, see above, in which it is rostral). Among euselachian sharks, the attachment is ventral in the superfamily Scylloidea, and a ventral attachment is found in the protoselachian Port Jackson shark (*Heterodontus*). These results all correlate well with current taxonomical classification. The only inconsistency appears in the superfamily Notidanoidea of euselachian sharks, since in *Hexanchus* and *Heptranchias* the attachment is dorsal[4], whereas in *Chlamydoselachus* it is ventral[5]. The site of superficial attachment of the nervus terminalis may not be of particular taxonomical significance; but it serves to illustrate how accumulated observations might be used to corroborate or to modify taxonomical classification, and how even apparently trivial descriptive details may be seen to have meaning when viewed in the light of taxonomy.

A suggestion for more attention by biological investigators to taxonomy must, unfortunately, be accompanied by a plea for the devotion of more precision and care to the use of correct generic[6] and specific[7] names.

Information Gain in Tasks involving Different Stimulus-Response Relationships

IN an attempt to clarify issues raised by changes associated with age in the ability of human subjects to perform perceptual-motor tasks, the rates of information transmission of younger and older subjects in performing discrete, choice reaction time tasks involving two different stimulus-response relationships were calculated. The tasks involved moving a stylus as quickly as possible from a central point to one of a number of targets arranged in a semi-circle in response to the appearance of one of a number of signal lights arranged in a similar semi-circle. The first (direct) stimulus-response relationship required subjects to aim at targets corresponding directly in position to signals which appeared. In the second, indirect version of the task, the correct target was the 'mirror image' of that directly indicated by the signal.

It was found that: (1) in all cases, the mean reaction time of subjects was proportional to the amount of information conveyed by the signal; (2) rate of information transmission was lower in both younger and older subjects when the stimulus-response relationship was indirect; (3) in both stimulus-response relationships, the rate of information transmission of older subjects was lower than that of younger subjects. The first of these findings is in line with those of Hick[1], Hyman[2] and others, and the second confirms work by Crossman[3] and others. In these previous studies, however, age was not treated as an experimental variable. The third finding supports a hypothesis of Welford[4] in explanation of age changes in perceptual-motor performance, that the ability to process information centrally deteriorates with age.

The calculated rates of information transmission were derived from the a constants in the functions which were found to fit the mean reaction time data in all cases. These functions all took the general form:

$$R.T. = a \log_2 \frac{1}{p} + b \qquad \text{(I)}$$

where $R.T.$ is the mean reaction time (sec.) to signals the probability of occurrence of which is p. Calculated rates of information transmission were given by the formula:

$$R = \frac{1}{a} \qquad \text{(II)}$$

where R is mean rate of information transmission (bits/sec.).

The specific forms these regressions took were as follows:

Direct S–R relationship	Younger Ss	$R.T. = 0{\cdot}073 \log_2 \frac{1}{p} + 0{\cdot}288$	(III)
	Older Ss	$R.T. = 0{\cdot}094 \log_2 \frac{1}{p} + 0{\cdot}307$	(IV)
Indirect S–R relationship	Younger Ss	$R.T. = 0{\cdot}127 \log_2 \frac{1}{p} + 0{\cdot}296$	(V)
	Older Ss	$R.T. = 0{\cdot}171 \log_2 \frac{1}{p} + 0{\cdot}301$	(VI)

These results lend themselves to interpretation in an interesting manner. The calculation of rates of information transmission on the basis of the a constants of equations (III) to (VI) suggests that in the indirect version of the task lower rates applied than in the direct version. This implies that the information-processing capacity of the human operator varies from task to task, which, on purely *a priori* grounds, is a somewhat unsatisfactory view. This difficulty may be avoided if it is recognized that equations (V) and (VI) may be re-written in such a manner as to retain the values of the a constants present in equations (III) and (IV), respectively. Equation (V), re-written in this manner, would be:

$$R.T. = 0{\cdot}073 \left\{\frac{0{\cdot}127}{0{\cdot}073}\left(\log_2 \frac{1}{p}\right)\right\} + 0{\cdot}296 \qquad \text{(VII)}$$

and equation (VI), re-written, would be:

$$R.T. = 0{\cdot}094 \left\{\frac{0{\cdot}171}{0{\cdot}094}\left(\log_2 \frac{1}{p}\right)\right\} + 0{\cdot}301 \qquad \text{(VIII)}$$

The implication of these re-written equations is that it is not the rate of information transmission which varies from task to task but the amount of information conveyed by signals. In the indirect version of the task, this is increased by the factor by which the expression $\log_2 1/p$ is multiplied. Further, the approximate equality of these factors in equations (VII) and (VIII), 1·74 and 1·80, respectively, suggests that to both younger and older subjects the amount of information conveyed by signals is increased to the same extent.

While involving a modification of the conventional use of information theory in the interpretation of psychological data, the interpretation proposed above appears to represent a useful descriptive foundation upon which the interpretation of data obtained under different conditions of stimulus-response coding may be based. Full details of the experiment and a fuller discussion of the interpretation proposed here will appear elsewhere.

After-Effect of Movement produced by a Rotating Spiral

Following visual stimulation by a rotating spiral, a negative after-effect of movement is observed. A preliminary report on what variables are relevant has been made by Holland[1]. Eysenck, Holland and Trouton[2] have since claimed that individual differences in length of after-effect conform to predictions from Eysenck's theory. In view of these claims and of the fact that others[3,4] are using this phenomenon in a clinical diagnostic context, it is perhaps important to offer this progress report of further experiments on the extent of normal variation and the factors influencing it.

The number of subjects participating in these experiments was eighty. The spiral was of the same pattern as that used by Eysenck, Holland and Trouton[2]. The principal findings may be summarized as follows:

The variables influencing the duration of the after-effect (*other than individual differences*).

(1) Duration of after-effect is very resistant to changes in illumination over a wide range (approximately 120–20 ft. candles on the surface of the spiral with the subject seated about 5 ft. away) ($N = 30$). Between 27 and 0·4 ft. candles there is a slight drop in mean duration from 10 sec. to 8 sec. ($P > 0{\cdot}05$), but it is substantially unaltered until the spiral is so dim that fusion occurs during rotation, and it is then destroyed ($N = 10$).

(2) Continuous trials cause a decrement in the duration of after-effect. There is a difference between the same condition repeated at the beginning and end of a series of thirteen intervening measurements ($P > 0{\cdot}01$). The same condition, repeated at random among the thirteen, had a mean value midway between the two extremes ($N = 23$).

These findings confirm and extend previous work[1,2], whereas the following observations are discrepant.

(3) Length of stimulation results in increase in the duration of effect over the whole range tried (5 sec.–10 min.). Subjects with persistent after-effects tend to show greater proportional as well as actual gain; for example, between $2\frac{1}{2}$ and 5, and 5 and 10 min. stimulation there is a gain of more than $\frac{1}{2}$, compared with 1/3 and 1/5 respectively in those with very short after-effects ($N = 45$).

(4) The after-effect is shorter using a spiral 3 in. in diameter than one 6 in. in diameter ($P > 0{\cdot}05$, $N = 18$). It is also shorter than when using a disk 12 in. in diameter but not significantly so ($N = 21$).

(5) Of twenty-five subjects only nine were able to view the spiral monocularly and observe the after-effect with the unstimulated eye. Five did so in one direction only, and the other eleven did not find any transfer of the effect. Duration of after-effect tends to be less, but not in all subjects.

(6) Twenty-three out of the twenty-five subjects were able to observe the after-effect on a relatively unstructured surface—a black card. Duration of after-effect differs for individuals from that under the usual conditions of observation, but there is no overall diminution.

Further experiments showed:

(7) That the wave-length of light in which the spiral is viewed has no effect ($N = 11$).

(8) There is no difference produced by contracting and expanding spirals ($N = 20$).

(9) Rotation at 16 r.p.m. produces a significant decrease compared with 45 and 78 r.p.m., between which there is no difference ($P > 0{\cdot}001$, $N = 22$).

(10) Fixation of a point on the periphery of a spiral 12 in. in diameter produces marked decrement compared with fixation of the centre ($P > 0{\cdot}001$) and similarly for fixation of a point 10 in. away from the centre of a spiral 3 in. in diameter ($P > 0{\cdot}01$, $N = 22$).

(11) Monocular viewing slightly decreases the after-effect. Values for each eye separately are lower than for both together ($P > 0{\cdot}1$, $N = 18$).

(12) Striking subjective colours are reported by some subjects, especially with prolonged stimulation, and there is a considerable degree of consistency in the quality and location of the colours seen under particular conditions.

The effect of individual differences. Contrary to previous assertions[2], no significant differences at any of eight different periods of stimulation were found between the 12 most extroverted and 12 most introverted subjects, selected by their extroversion scores on the Maudsley Personality Inventory[6] from a group of 76.

Diagnostic value. Previous studies, using as criterion the presence or absence of after-effect, report varying percentages of organics who perceive the after-effect; however, none of the studies[4,5] using normals as controls reports complete failure to see the effect by any of the normal group. Thus there is recognized to be overlap between organics and normals in their ability to see the effect, but not in failure to see it. Of our eighty subjects, however, four saw no after-effect, even after prolonged stimulation, and it therefore seems unwise to assume that absence of the effect is evidence of brain-damage.

Holland and Beech[5] have suggested that the duration of after-effect may discriminate between normal subjects and those with brain damage. Apart from the four mentioned above, there were nine subjects in whom duration of after-effect was below that reported by Holland and Beech as the minimum for their normal group, and which, taken as a cut-off point, identifies eight out of their 21 organics without misclassification. 16 per cent of the 'normal' subjects in this study would, on this basis, be diagnosed as having brain damage.

In view of various discrepancies between these results and those previously reported, further work would seem necessary before anything can be asserted about the nature of the individual differences related to differences in length of after-effect, or about the diagnostic value of this phenomenon.
